One of the likely reasons for the lack of change in the epidemiology of lung cancer in India (and possibly other developing countries) is the fact that the most common smoking product is not cigarette, but *bidi*- the hand rolled form of tobacco wrapped in the dried tendu leaf.[15] In a large Indian multicentric study conducted recently, the ratio of *bidi* to cigarette smoking was 2.6:1 overall and 6.5:1 in the rural areas.[15] The process of *bidi* manufacturing is primarily a cottage industry and has changed little with time unlike that for cigarettes. Moreover, quit rates for smoking continue to be less than 10% in India.[15] Therefore, an absence of change in the smoking pattern of the Indian population may be another reason for the lack of change in the epidemiology of lung cancer. After the recent initiation of vigorous anti-tobacco measures under the national tobacco control program, there is a possibility that, the ratio of smokers to never-smokers as well as the distribution of different types of smoking products may change with time and this may ultimately lead to a change in the clinical-epidemiological profile of lung cancer presentation. However, such a change is likely to occur only after a lag of several years to a few decades, which reflects the time period needed for any intervention related to smoking cessation to have its effect on a disease linked to chronic tobacco consumption.

An important difference in the pathogenesis of the various histological types of lung cancer is in relation to their site and cell of origin. The conducting bronchial airways are the site of origin of almost all cases of SqCC and SCLC. The basal bronchial cell, a candidate stem cell, is believed to be the cell of origin for these histological types.[16] A small proportion of cases of ADC can also arise in this way. However, majority of ADC have their origin in the peripheral compartment of the lung primarily the terminal respiratory unit, respiratory bronchioles and the alveoli. Herein the bronchioloalveolar cell, another putative stem cell, is thought to be the cell of origin. This cell is also believed to give rise to Clara cells and type II pneumocytes.[16]

During the process of development of SqCC, genetic and environmental triggers lead to the changes in the normal bronchial epithelium, often in a stepwise manner, with the formation of hyperplastic, metaplastic and dysplastic lesions. Continuous oncogenic stimuli ultimately lead to the development of carcinoma in situ and frank SqCC. In the case of ADC, a similar mechanism is believed to be operating, since atypical adenomatous hyperplasia (AAH) is a premalignant lesion and often precedes the development of overt ADC.

RISK FACTORS

Risk factors having proven or possible association with lung cancer are elaborated in Table 115.2.

Tobacco Smoking

Tobacco smoking is the most common risk factor for lung cancer. The majority of lung cancers including approximately 85% of Non-Small Cell Lung Cancer (NSCLC) and 98% of SCLC cases arise in smokers. Several carcinogens have been identified in tobacco smoke and strong associations for a few of them [including Polycyclic Aromatic Hydrocarbons (PAH) and nicotine-derived

TABLE 115.2: List of risk factors that have proven or possible associations with lung cancer

Tobacco Smoking (Active)
Environmental tobacco smoke (ETS) exposure
Pulmonary Diseases
- Chronic obstructive pulmonary disease (COPD)
- Idiopathic pulmonary fibrosis (IPF)
- Systemic sclerosis related interstitial lung disease
- Pneumoconiosis

Systemic Diseases
- HIV infection

Air pollution (indoor and outdoor)
- Domestic cooking fuels
- Petroleum product combustion exhaust exposure

Environmental exposures
- Radon
- Arsenic, nickel, chromium
- Asbestos

Dietary factors
- Alcohol consumption
- Intake of vitamins, fruits and vegetables

Hormone therapy
Genetic factors
- Familial (hereditary)
- Specific gene abnormalities (non-hereditary)

nitrosoaminoketone], have been observed with the occurrence of lung cancer. These carcinogens are responsible for the development of genetic mutations through formation of deoxyribonucleic acid (DNA) adducts.

In a case control study conducted at the author's institute, an evaluation of the role of tobacco smoking in relation to the occurrence of lung cancer was undertaken.[17] Ever-smoking was associated with odds ratio (OR) of 5.0 [95% confidence interval (CI) = 3.11-8.04] among men and 2.47 (95% CI = 0.79 to 7.75) among women for occurrence of lung cancer. Among the patients, men were found to smoke a higher average number of cigarette-equivalents per day, for longer duration and started at an earlier age as compared to controls. Interestingly, tobacco smoking in traditional Indian forms (*bidi* and *hookah*) was associated with similar ORs as compared to cigarette smoking implying that tobacco smoking is equally bad in its various forms. In a subsequent study performed at this institute aimed at evaluating the risk factors associated with development of lung cancer among females, it was observed that the odds were highest for active tobacco smoking (OR = 4.87; 95% CI = 1.34-17.76) although majority (74.6%) of the subjects (females) were nonsmokers.[18] Therefore, in the Indian context and possibly elsewhere in the world also wherein a similar socioeconomic profile is present, active tobacco smoking is the principal risk factor responsible for causation of lung cancer among men while several other risk factors besides smoking are important in the case of women.

Lung Cancer in Never-smokers

An estimated 10 to 15% of lung cancer related mortality is related to factors other than active smoking. Moreover, majority of the cases of lung cancer attributable to such factors occur in never-smokers. Lung cancer occurring among never-smokers is believed to be different from that occurring among smokers and this hypothesis is supported by differences in the molecular profile seen in the two groups.[19] Lung cancer among never-smokers (often referred to as nonsmokers) arises in the peripheral compartment, in contrast to smokers where it occurs in the central compartment. Important risk factors for occurrence of lung cancer among never-smokers include Environmental Tobacco Smoke (ETS) exposure as well as exposure to outdoor and indoor air pollutants, several of whom can induce, promote and propagate the process of carcinogenesis. Despite this, in several cases, a clear etiological agent(s) may not be identifiable since the available data on the association of such factors with occurrence of lung cancer is not as strong as it is for active tobacco smoking and several exogenous carcinogens remain poorly defined.

ETS Exposure

A case-control study was conducted previously at the author's institute to assess the relationship between exposure to ETS and occurrence of lung cancer in lifetime never-smokers.[20] Assessment of ETS exposure from different tobacco products during childhood at home and during adulthood at home, at work place and inside vehicles was made. Overall, an increasing risk for lung cancer was found with increasing number of smokers and duration of exposure. A strong association was observed between ETS exposure during childhood and lung cancer [OR = 3.9; 95% CI = 1.9-8.2]. In relation to adult life, the increased risk due to ETS exposure from a smoking spouse was observed only in case of cigarette smoke (OR = 5.1; 95% CI = 1.5 to 17). Exposure to ETS inside vehicles was also detected to be a risk factor (OR = 5.2; 95% CI = 1.9 to 14).

Indoor Pollution

Indoor pollution due to domestic cooking fuels has also been implicated as a causative agent in lung cancer especially among women. In a case control study at the author's institute, information about exposure to various cooking fuels was obtained from women using a questionnaire.[18] Among non-smokers, the risk of development of lung cancer was highest for biomass fuel exposure [OR = 5.33; 95% CI = 1.7-16.7]. This risk persisted (OR = 3.59; 95% CI = 1.07-11.97) even after adjustment for smoking and ETS exposure was made in multivariate logistic regression analysis. Use of mixed fuels was associated with a lesser risk (OR = 3.04; 95% CI = 1.1-8.38).[18] Duration of exposure is an important determinant as was seen in one study wherein cumulative exposure of greater than 45 years to indoor air pollution from use of coal or wood for cooking or heating showed an OR of 1.43 (95% CI = 0.33-6.30) for the development of lung cancer.[17]

It has been demonstrated that wood smoke exposure can produce similar molecular effects on p53 tumor suppressor gene as tobacco and thus be an important risk factor for lung cancer among never-smokers.[21]

Socioeconomic Profile

In a systematic review and meta-analysis of published literature, the association between various socioeconomic indicators and lung cancer incidence was evaluated.[22] On analysis of 64 studies which were eligible for inclusion, an overall increased risk in lung cancer incidence was observed among people with low socioeconomic profile. Two important observations were noted in this article. Firstly, the increased risk persisted even after adjustment for smoking status, a potentially important confounder. Secondly, the increase in lung cancer incidence was observed in three different aspects of socioeconomic profile namely educational, occupational and income-based with the association being strongest for the former and weakest for the latter.[22]

Analyses of a subsample of the European Prospective Investigation into Cancer and Nutrition (EPIC) study was conducted to determine the extent to which occupational exposures could influence the socioeconomic inequalities in lung cancer incidence.[23] In this, exposure to three carcinogens {asbestos, heavy metals and PAH} was analyzed. These occupational exposures could account for 14% of the socioeconomic inequalities remaining after adjustment for tobacco smoking and dietary factors (fruits and vegetables consumption).

Enviromental Exposures to Minerals and Metals

Arsenic has been identified as a lung carcinogen in humans. In a geographically defined cohort study, more than 10,000 subjects residing in arseniasis-endemic areas were followed up for an average period of eight years.[24] After adjustment for cigarette smoking and other risk factors, a significant dose-response trend was observed between level of arsenic in drinking water and lung cancer. The relative risk for the highest arsenic level, as compared with the lowest, was 3.29 (95% CI = 1.60-6.78). Lung cancer was attributable to the joint exposure of ingested arsenic and cigarette smoking in 32 to 55% of cases. A synergistic effect of ingested arsenic and cigarette smoking on occurrence of lung cancer was also noted. Chromium, nickel and asbestos are other important carcinogens.

Radon has been associated with lung cancer among miners working under ground. However, even the general population remains at risk due to exposure to indoor radon and its decay products. The risk of lung cancer from this environmental exposure is in the form of a linear dose-response relationship with no threshold.[25] In certain areas, radon is believed to be the second main causative agent for lung cancer, after tobacco smoking, in the general population without any other form of occupational exposure. This has important implications for disease prevention, since it is important to identify buildings which have high radon concentrations.

Petroleum Product Combustion

The association of petroleum product combustion with lung cancer has also been evaluated. In particular, use of diesel for power generation became very common in the 1950s and till 1990, exhaust from its combustion was 100 fold compared to current levels using newer technology. In a recent review, the possible link between particulate matter in diesel exhaust and lung cancer was assessed.[26] However, majority (24) of the 34 studies had either indeterminate or negative trends while only ten showed a positive trend in exposure-response analyses. Moreover, it could not be ascertained even in the small number of positive studies, whether the association was causal in nature or not.

Alcohol Consumption

Analysis of the Environment and Genetics in Lung Cancer Etiology (EAGLE) Study, a population-based case-control study, was done to investigate the relation between alcohol consumption and lung cancer.[27] Consumption of alcohol during adulthood was assessed in 1,855 cases and 2,065 controls. Interestingly, both non-drinkers [OR = 1.42; 95%; CI = 1.03 to 2.01] and very heavy drinkers ($\geq$60 gm/day; OR = 1.44; 95% CI = 1.01 to 2.07) were at significantly greater risk than very light drinkers (0.1 to 4.9 gm/day). However, the alcohol effect was confounded by smoking behavior since no excess risk was observed among never-smokers on multivariate analysis. This was a hypothesis generating study since it suggested the possibility of an interaction between alcohol consumption and tobacco smoking in relation to occurrence of lung cancer.[27]

Hormone Use

Association between hormone use and lung cancer among women was assessed in a prospective study involving 2,861 women aged 31 to 79 years with a follow- up period of approximately 30 years.[28] Overall, this study did not find any association between hormone use and lung cancer (hazard ratio = 1.13; 95% CI = 0.73-1.73). Even on analysis after stratification by age (55 years being taken as an approximate cut off for menopausal status), the results did not reach statistical significant. However, divergent results were observed with a trend for higher risk among women aged 55 years or above and for a lower risk among women younger than this age.

Structural Lung Disease

Structural lung disease is believed to be a predisposing factor for the development of lung cancer. Idiopathic Pulmonary Fibrosis (IPF) is one of the important disorders in this group. In a retrospective longitudinal cohort analysis, the cumulative incidence of lung cancer after the diagnosis of IPF was assessed.[29] During the observation period, 20.4% patients developed lung cancer. The cumulative incidence rates increased as the duration of follow-up increased being 3.3%, 15.4% and 54.7% at 1, 5 and 10 years respectively. Systemic sclerosis and other causes of interstitial lung disease as well as old scars of pulmonary tuberculosis and other infections have been occasionally implicated to predispose to the development of lung cancer.

Human Immunodeficiency Virus (HIV) Infection

Lung cancer risk is substantially elevated in HIV-infected individuals as compared to the general population. However, there are two important features in relation to HIV related lung cancer. First, the risk is unrelated to HIV-induced immunosuppression.[30] Second, smoking does not account for all of the increase seen in the incidence of lung cancer – the higher risk being present even after adjustment for smoking.[30,31] The other factors responsible for the increased incidence remain poorly identified as of now.

Genetic Factors

Familial aggregation of cases has also been documented in literature. In a case control study conducted at the author's institute, patients with lung cancer were more likely than controls to have relatives with cancers [OR = 1.27; 95% CI = 0.49 to 3.10] both among smokers and non-smokers (OR = 1.31; 95% CI = 0.27 to 6.79 and OR = 1.21; 95% CI = 0.12 to 6.16 respectively).[32] Sisters of cases, in particular, had a higher risk (OR = 8.72; 95% CI = 0.85 to 430.08). This study lends credence to the suggestion that genetic factors perhaps are independent risk factors for the occurrence of lung cancer.

MOLECULAR BIOLOGY

Several genetic alterations, elaborated in Table 115.3[33] have been observed in lung cancer. The main molecular mechanisms observed in its pathogenesis include abnormalities in growth-stimulatory signaling pathways, abnormalities in tumor suppressor gene pathways, evasion of apoptosis and epigenetic changes (Table 115.4).[16] In some cases of NSCLC, a single specific mutated oncogene can act as the primary genetic "driver" responsible for the pathogenesis of cancer. The two most commonly mutated oncogenes in lung cancer

TABLE 115.3: List of genetic alterations observed in lung cancer (modified and adapted from Sato et al)[33]

Gene	*Type of Alteration*
Epidermal growth factor receptor (EGFR)	Mutation, amplification
HER-2	Mutation, amplification
RAS	Mutation
p53	Mutation, deletion
PI3K/AKT/mTOR	Constitutively activated
MEK	Constitutively activated
Vascular Endothelial Growth Factor (VEGF)	Over-expression
Telomerase	Over-expression
BCL-2	Over-expression
c-Kit	Over-expression

are the Epidermal Growth Factor Receptor (EGFR) gene and KRAS gene.

EGFR Expression

The EGFR family of genes encodes widely expressed transmembrane tyrosine kinase molecules. On activation by the ligand, these receptors signal through the RAS-RAF-mitogen activated protein kinase and phosphatidylinositol 3-kinase pathways and play a key role in regulating cell proliferation and survival (Fig. 115.1). Mutation or hyperexpression of these receptors are responsible in lung cancer for their oncogenic activation, favoring proliferation, differentiation, apoptosis and angiogenesis. The most common EGFR mutations observed are exon 19 deletion and exon 21 L858R point mutation. In the latter, leucine at amino acid 858 is replaced by arginine.

KRAS Mutations

The RAS genes encode a family of membrane-bound 21-kd Guanosine Triphosphate (GTP)-binding proteins, which by interacting with multiple effectors, are involved in the regulation of cell growth, differentiation, and apoptosis. KRAS mutations are known to occur in 20 to 30% of NSCLCs.[34] These mutations lead to impaired

TABLE 115.4: Molecular mechanisms of pathogenesis of lung cancer (modified and adapted from Brambilla et al)[16]

Abnormalities in growth-stimulatory signaling pathways

- Epidermal growth factor receptor (EGFR) signaling pathway
  - EGFR deregulation
  - Mutations in other EGFR signaling pathway genes - KRAS
- Anaplastic lymphoma kinase (ALK) fusion proteins
- Thyroid transcription factor 1 (TTF-1)
- Myc family

Abnormalities in tumor suppressor gene pathways

- p53 pathway
- p16INK4/cyclin D1/Rb pathway
- Serine/threonine kinase 11 gene

Evasion of apoptosis

- Altered regulation of mitochondrial apoptosis (Bax/Bcl-2 imbalance)
- Deregulation of death receptor (Fas-FasL) pathway
- Inappropriate telomerase activity

Epigenetic changes

- DNA methylation and hypermethylation
- Epigenetic modifications (change in acetylation and/or methylation status) of histones
- Somatic mitochondrial DNA (mtDNA) mutations
- MicroRNAs–dysregulation and/or specific expression patterns

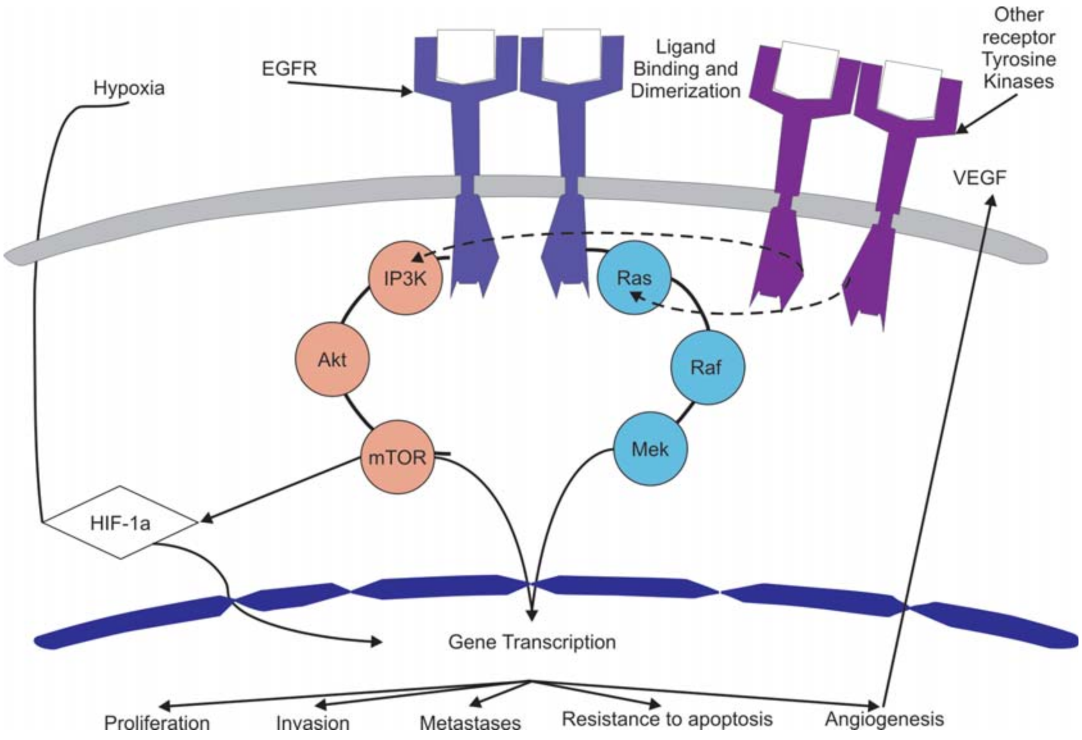

Fig. 115.1: Downstream EGFR signaling pathways through the RAS-RAF mitogen-activated protein kinase pathway and PI3K/AKT pathway

GTPase activity, which is located downstream of EGFR and consequently constitutive activation of RAS signaling.

Comparison of Mutations in EGFR and KRAS Genes

There are several differentiating features between mutations in these two genes. First, EGFR mutations are more commonly found in never-smokers in contrast to KRAS mutations which are commonly present in those with significant tobacco exposure.[35] Second; these mutations determine sensitivity to drugs that target the EGFR signaling pathway. Anti-EGFR molecules like gefitinib and erlotinib are important drugs among the targeted therapies available for treatment of NSCLC and act by blocking EGFR receptor mediated signals which in turn prevent downstream events mediated by RAS and other effector molecules. EGFR receptor blockade ultimately leads to inhibitory effects on tumor cell survival and proliferation.

On the other hand, in the presence of KRAS mutations, as opposed to wild type KRAS gene, KRAS mediated effects are permanently "turned on" and downstream signals occur despite blockade of EGFR allowing the tumor cells to survive and proliferate.[36] Presence of KRAS mutations is therefore an important factor which determines lack of responsiveness to anti-EGFR drugs.[37] Lastly, EGFR and KRAS mutations also serve as prognostic factors with better overall survival being observed in patients having EGFR mutations than those whose with KRAS mutations.[35] Thus, mutations in these two genes are believed to represent subgroups of patients with NSCLC with different natural histories as well as responses to targeted therapy.[36]

Fragile Histidine Triad Gene

The Fragile Histidine Triad (FHIT) gene plays an important role in the pathogenesis of lung cancer. Alterations in the FHIT gene in the form of loss of heterozygosity and complete/partial gene methylation were observed in 100 and 84% of cases.[38] The latter was also observed to be associated with loss of FHIT mRNA expression.

Angiogenesis and Role of Vascular Endothelial Growth Factor (VEGF)

Angiogenesis, the formation of new tumor-feeding blood vessels, from pre-existing vasculature, is critical for the development and growth of tumors and subsequently for invasion and metastasis. Angiogenesis is regulated and determined by the balance between pro-angiogenic and anti-angiogenic factors released by tumor cells and adjacent host cells. However, after a variable period of time, with ongoing growth of tumor cells, the balance shifts in favor of the pro-angiogenic response. This results in endothelial cells growing from nearby blood vessels, crossing the basement membrane and migrating into the tumor mass wherein they undergo proliferation leading to formation of capillaries. However, these are and often leaky. However, neovascularisation is characterized by presence of blood vessels that are qualitatively poor, heterogeneous and leaky. Not only do they contain disorganized and irregularly shaped endothelial cells, the basement membranes are also abnormal.[39]

Proteins encoded by the Vascular Endothelial Growth Factor (VEGF) family of genes are the predominant pro-angiogenic factors. The VEGF family of growth factors is comprised of several structurally related molecules, including VEGF-A, VEGF-B, VEGF-C and VEGF-D. VEGF-A, commonly referred to as just VEGF, is one of the most important in this group. Its binding to the VEGF receptor (VEGFR-2) leads to activation of multiple signaling pathways, as well as up-regulation of genes which promote the proliferation and migration of endothelial cells as well as vascular permeability.[40] Targeting the VEGF pathway has become an important addition to the armamentarium available for the treatment of NSCLC since bevacizumab (a humanized monoclonal antibody directed against VEGF) has been shown to increase overall survival of patients with advanced non-squamous NSCLC when administered in combination with standard platinum based doublet chemotherapy.[41]

Evasion of Apoptosis

The Bcl-2 family of proteins plays a critical role in the regulation of apoptosis and changes in this pathway can lead to altered ratio of pro- and anti-apoptotic molecules and consequently development of lung cancer. Bcl-2 (anti-apoptotic) and Bax (pro-apoptotic) are key regulators of mitochondrial apoptosis. Bcl-2 overexpression has been observed in lung cancer especially SCLC. A positive association of p53 (a tumor suppressor gene) with Bax expression has been demonstrated in bronchial biopsy specimens obtained from patients with locally advanced squamous cell carcinoma of the lung.[42]

Another mechanism for evasion of apoptosis is via the death receptor pathway. The death receptor (Fas) activates a signaling pathway on binding to its ligand (FasL) leading to apoptosis. The Fas receptor and FasL are down-regulated in a majority of cases of NSCLC.

Telomeres are repetitive sequences (TTAGGG repeats) that are located at the end of chromosomes. They protect chromosomes from degradation and loss of essential genes. Under normal circumstances, telomeres shorten after each round of cell division. When critical shortening of telomeres occurs, it leads to induction of apoptosis or cellular senescence. The enzyme telomerase maintains telomeres by elongating telomeric DNA through the process of reverse transcription. Telomerase gene over-expression is another molecular abnormality observed in lung cancer. Telomerase activity in sputum correlates with that observed in bronchial biopsy specimens. Sputum telomerase activity has been shown to have sensitivity, specificity, negative predictive value and positive predictive value of 67.6%, 90%, 71% and 88.46% respectively for the diagnosis of this disease and thus is a candidate non-invasive biomarker.[43]

Other Molecular Abnormalities

Microsatellites of DNA are tandem repeats of 1 to 6 nucleotides that are normally found at different locations in the human genome. Microsatellite Instability (MSI) refers to the phenomenon of expansions and contractions of these tandem repeats that is observed as an early genetic alteration during the process of carcinogenesis. Deletion of one allele of a pair at specific chromosomal loci is known as Loss of Heterozygosity (LOH). Microsatellite instability and LOH correlate with high mutational rates in tumor cells. Both these microsatellite alterations (MSI and LOH) have been observed in DNA extracted from bronchial washings and tumor specimens obtained on bronchoscopy.[44] Detection of these alterations provides better sensitivity than conventional cytology for the diagnosis of lung cancer.

An important understanding has been made in the last decade with the identification of a new mode of gene regulation in the form of non-coding RNAs termed microRNAs (miRNAs or miRs). These molecules are very short (approximately 19 to 22 nucleotide) single stranded RNAs that are involved in the process of gene regulation by either causing induction of mRNA degradation or inhibition of translation.[45] MicroRNAs can regulate several genes simultaneously and thus cellular processes and pathways (like apoptosis, development, proliferation and differentiation). Dysregulation as well as discrete patterns of miRNA expression have been observed in lung cancer in both *in vivo* and *in vitro* studies.

Pathology of Lung Tumors

Ashim Das

INTRODUCTION

Classification of lung tumor based on histopathological examination has remained debatable. A standardized nomenclature and uniform criteria for diagnosis helps not only in maintaining consistency in diagnosis and treatment but also gives uniformity in epidemiologic and molecular studies. Only morphological aspects by routine light microscopy are taken into account for classification. In addition to H and E stain, a simple mucin stain is only used for this classification of lung tumors. Most of the time, a minimum use of ancillary techniques are used for this purpose.

According to the World Health Organization (WHO) Classification (2004), malignant epithelial lung tumors are divided into five major groups (Table 116.1).[1]

TABLE 116.1: Classification of malignant epithelial tumors of lung

1. Squamous cell carcinoma
2. Adenocarcinoma
3. Small cell carcinoma
4. Large cell carcinoma
5. Carcinoid tumors

MINOR GROUPS

- Sarcomatoid carcinoma and salivary gland tumors
- Adenosquamous carcinoma

Most of the malignant tumors develop through a phase of preinvasive component. The preinvasive lesions are:

1. Squamous dysplasia/carcinoma *in situ*
2. Atypical adenomatous hyperplasia
3. Diffuse idiopathic neuroendocrine cell hyperplasia

These three preinvasive lesions are recognized in WHO classification, as these may progress to invasive neoplasm.

Squamous Dysplasia—Carcinoma *in Situ*

Many small cell carcinomas may arise through this type of alterations. Basal cell hyperplasia, goblet cell hyperplasia and squamous metaplasia are also identified as earlier changes of dysplasia/carcinoma *in situ* changes of squamous epithelium of central airways.

Basal cell hyperplasia is defined as the presence of three or more layers of basal cells without any evidence of keratinization or intercellular bridges but lacking cellular atypia.

Goblet cell hyperplasia is characterized by excessive numbers of mucus secreting goblet cells in the respiratory epithelium.

Squamous metaplasia is recognized by the replacement of full thickness of respiratory epithelium by squamous cells.

In squamous dysplasia/carcinoma *in situ*, four grades are recognized. Macroscopically, these areas could be pale with loss of transparency, vague nodularity or granularity can be seen. The grading of squamous dysplasia depends on the presence of atypia in the different layers of epithelium with increasing severity of cellular and nuclear pleomorphism. Maturation of cells and cellular orientation are also taken into account in categorizing the different grades. Among the nuclear features, nuclear-cytoplasmic ratio with finely granular to thick coarse chromatin pattern along with increase in number of mitotic figures are important for the recognition of different grades of squamous dysplasia/carcinoma *in situ*.

Mild dysplasia; is characterized by minimal architectural and cytological atypia limited to the lower third of lung with absent or rare mitosis. Moderate dysplasia shows cellular crowding in the lower two-thirds of the epithelium with mild pleomorphism and anisocaryosis with mitosis observed in lower third. On the other hand, severe dysplasia is characterized by marked cytological atypia involving even the upper third with mitotic figures observed in the lower two-thirds. However, a progression of maturation from base to surface can be seen.

Carcinoma *in situ* (CIS) does not show any progression of maturation towards the surface and is characterized by cellular crowding of the entire epithelium with widespread atypia along with the presence of mitotic figures in the full thickness of the mucosa.

Atypical Adenomatous Hyperplasia (AAH)

This has been recognized as a putative precursor of invasive adenocarcinoma. It is difficult to localize AAH lesions grossly without being subjected to proper inflation-fixation of lung. Microscopically, it is defined as "localized proliferation of mild to moderately atypical cells lining involved alveoli and sometimes, respiratory bronchioles, resulting in focal lesions in peripheral alveolated lung, usually less than 5 mm in diameter in the absence of interstitial inflammation". Usually, the interstitium is thickened in these areas with prominent alveolar epithelial cells, which could be cuboidal to low columnar to round in shape with admixing of peg cells with apical snouts. The size of AAH (<5 mm as proposed by WHO for the diagnosis of AAH) may be more than 5 mm even some authors have described lesions of AAH more than 5 mm as carcinoma.

AAH should not be diagnosed in the presence of lesions in which there is an injury to pneumocytes to distinguish it from reactive pneumocytic hyperplasia. AAH is usually diagnosed in a background of adjacent normal alveolar lining. It is also not true that the diagnosis of AAH cannot be done in a background of fibrosis and inflammation. In distinguishing AAH from localized non-mucinous bronchioloalveolar carcinoma (BAC), the features taken into account are as follows: A lesion with increased cell stratification and higher cell density with overlapping of nuclei having coarse chromatin with prominent nucleoli should be diagnosed as non-mucinous BAC. These lesions can show true papillae with cricket fence arrangement of cells and the height of the cells can exceed the normal heights of terminal bronchiole.

Diffuse Idiopathic Pulmonary Neuroendocrine Hyperplasia

This extremely rare lesion may develop into peripheral type of spindle cell carcinoid tumors. It is characterized by widespread proliferation of pulmonary neuroendocrine cells, not only as single cell but also in groups. A linear intraepithelial proliferation is also a characteristic feature. The nodules can project into the lumen with intact luminal lining and intact basement membrane.

EVOLUTION OF WHO CLASSIFICATION

One major change which has occurred in the 1999, WHO classification is the revision of the classification of neuroendocrine tumors and re-definition of bronchiolo-alveolar carcinoma. The introduction of preneoplastic process like atypical AAH and diffuse neuroendocrine hyperplasia is also an important feature in this classification.

The 2004 modification retains much of the same nomenclature as the 1999 edition and maintains the same major diagnostic groups with emphasis on morphologic features of diagnosis and the molecular biology of the various lung malignancies is also extensively covered.

Concept of Bronchioloalveolar Carcinoma (BAC)[2]

In the 1999/2004 classification, BAC is defined as an adenocarcinoma showing 'growth of neoplastic cells along pre-existing alveolar structures (lepidic growth) without evidence of stromal, vascular or pleural invasion (Fig. 116.1). Following this definition, resected localized non-mucinous BACs show 100% 5-year survival. Localized non-mucinous BACs probably evolve from foci of atypical AAH. Foci of stromal invasion are taken as a step towards the development of adenocarcinoma. Some authors commented that this could equally "well, or perhaps better, be considered as adenocarcinoma *in situ*". Hence, if there is an invasion, a diagnosis of BAC done solely based on the presence of a lepidic pattern somewhere in the lesion, could no longer be regarded as BAC. Bronchioloalveolar carcinoma, particularly the mucinous variant, may produce diffuse pneumonic

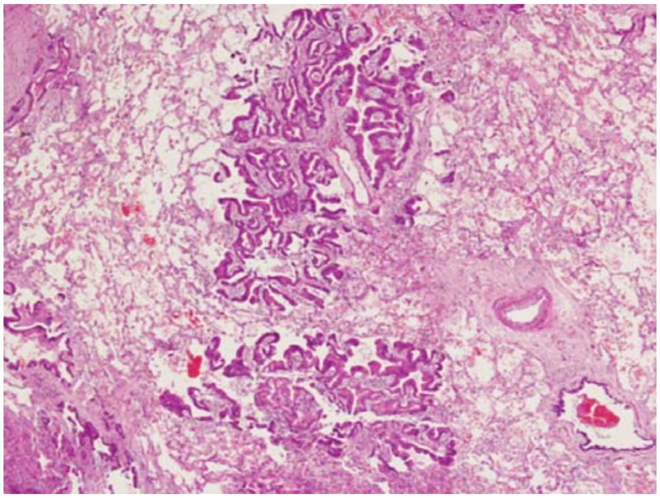

Fig. 116.1: Bronchioloalveolar carcinoma with lepidic pattern of growth, H and E

consolidation. Radiographically, peripheral adenocarcinomas produce a spectrum of ground-glass to solid opacities. The greater the solid component, the greater is the likelihood of an invasive growth component. The radiographic ground-glass component is correlated with the BAC component in pathology specimens.

Challenges Posed by 1999/2004 WHO Classification of Lung Adenocarcinomas[3]

The WHO classification is predicated on the histological examination of the whole of the tumor. The lung adenocarcinoma is a heterogeneous form of lung cancer and most of them are histologically variable, both between cases and within individual tumors. Small biopsy samples which are routinely used may not be representative of the whole tumor and the tumor architecture cannot be appreciated in a small biopsy. Most of the adenocarcinomas are diagnosed on small biopsy or cytology material, using a histological classification that is not really suited to this type of material. Hence, a subtyping of non-small cell carcinomas on small biopsy or cytology samples is not reliable with a relatively poor inter-observer agreement. A mucin stain can improve the figure. The subtype accuracy for adenocarcinoma based on biopsy material is much lower than squamous cell carcinoma. It has been found that most of the cases unclassifiable on small biopsy examination were adenocarcinomas in the surgically resected lung.

Traditionally, the epithelial tumors are divided into *non-small cell and small cell carcinoma* with a view that small cell carcinoma has a different mode of treatment than non-small cell carcinoma. The non-small cell carcinoma includes squamous cell, adenocarcinoma and large cell carcinoma. It is now believed that non-small cell carcinomas are heterogeneous both in molecular biology and also in treatment response.

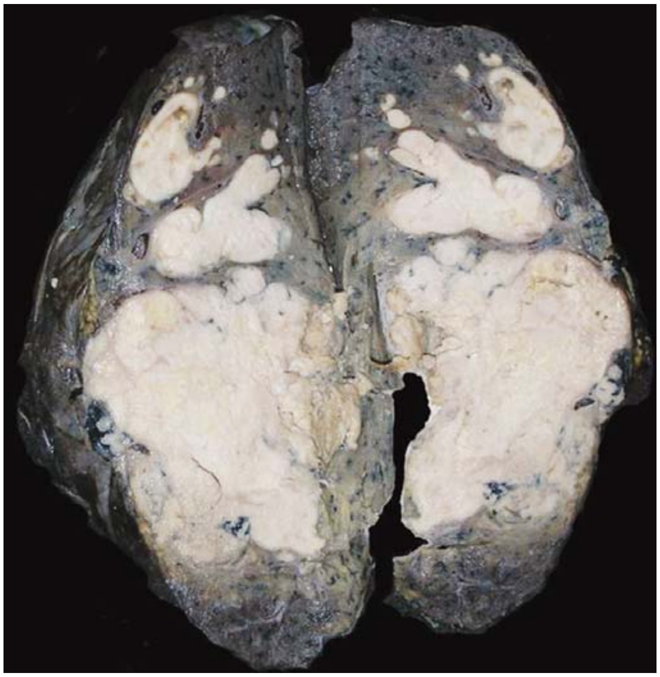

Fig. 116.2: Gross photo of squamous cell carcinoma

Squamous Cell Carcinoma (SCC)

Squamous cell carcinoma typically occurs as a central mass, but approximately 25% are located peripherally and 5% show central cavitation. Histologically, two features are important for diagnosis; keratinization and intercellular bridges (Figs 116.2 and 116.3). The WHO classification recognizes four variants namely; papillary, clear cell, small cell and basaloid. The small cell variant of squamous cell carcinoma is a poorly differentiated variant which contains small tumor cells but retains cellular characteristics of a non-SCC such as coarse chromatin, nucleoli and distinct cell borders.

Adenocarcinoma

The incidence of adenocarcinoma exceeds that of SCC in the developed countries. In our institute, the incidence of adenocarcinoma is increasing but not exceeding. Of a total of 606 cases of lung carcinoma, small cell carcinoma constituted 26.7%. Among the non-SCC (67.7%), SCC

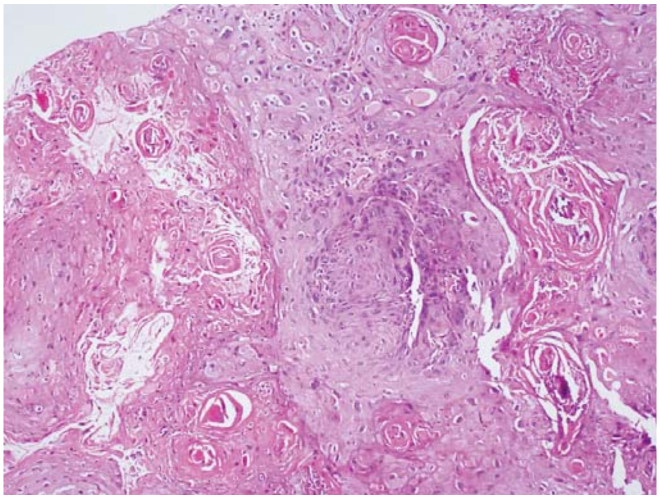

Fig. 116.3: Numerous squamous pearls with tumor cells showing keratinization. (H and E)

represented 71.2% whilst the adenocarcinoma constituted 17.6%. Also, a total of 28 cases were reported as non-small cell carcinoma without any further classification. Adenosquamous (6 cases) and large cell carcinoma (12 cases) constituted smaller groups.

Adenocarcinoma most commonly presents as a peripheral nodule and only rarely shows cavitation (Fig. 116.4). Occasional adenocarcinomas may present as a central or endobronchial tumor. Rare adenocarcinomas may produce a diffuse thickening of the visceral pleura, mimicking a mesothelioma. Histologically, mixtures of patterns are usually seen. These histological patterns may have different biological behavior with potential therapeutic applications for the patients. In fact, 80 to 90% of patients with adenocarcinoma show more than one histological pattern. A simple diagnosis of adenocarcinoma is thus not enough for diagnosis. All possible combinations of the four patterns, acinar (AC), solid (SOL), bronchioloalveolar carcinoma (BAC) and papillary (PAP) tumor can be seen (Figs 116.5 to 116. 7). The most common patterns are acinar and solid tumor. The BAC and solid patterns seemed to be least likely to coexist. The tumors that were predominantly BAC pattern were significantly smaller than those showing predominance of either a papillary or a solid pattern.

Criteria for Diagnosis of Pulmonary Adenocarcinomas

1. Tumor architecture in the form of gland formation in an intact fragment of tumor is essential for the diagnosis of adenocarcinoma.
2. Mucin secretion in two high-power (X400) fields of tumor, each containing at least five tumor cells with intracytoplasmic mucin is recommended for a diagnosis of solid adenocarcinoma with mucin.

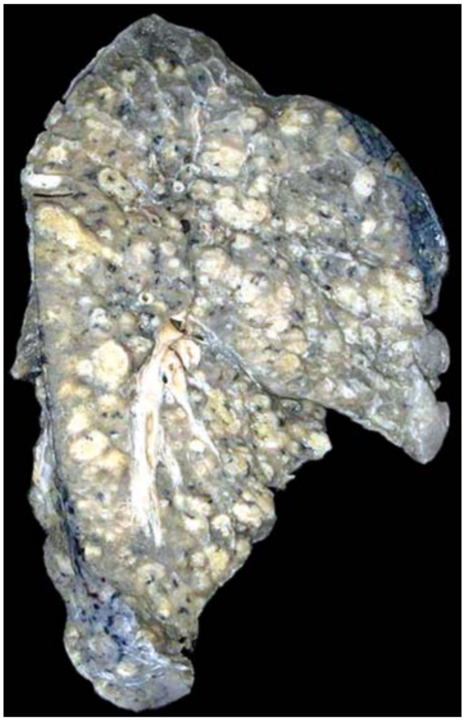

Fig. 116.4: Gross photo of adenocarcinoma with extensive nodular lesions

It is important to note that unequivocal squamous cell carcinomas may also show occasional cells containing mucin and there are no unique, reliable individual cytological criteria that allow diagnosis of adenocarcinoma. Immunohistological approaches to refining the separation of squamous cell from adenocarcinoma are potentially valuable, but they need to be measured against cell type classification on resected tumors and against appropriate clinical data and outcomes. Immunohistochemistry should not overwrite the histological classifications of lung tumors.

Small Cell Carcinomas [4,5]

It constitutes approximately 25% of usual lung cancers and it was also known as oat cell carcinoma or small cell neuroendocrine carcinoma. Grossly these tumors are centrally located in the majority of cases. It shows large areas of multifocal necrosis. Microscopically, in the majority of cases the bronchial or transthoracic core biopsy specimens, show an infiltrate of "small" cells with variable crush artefacts and nuclear smearing (Fig. 116.8). The character of the cells should be seen in the better preserved areas. The cells have round or fusiform nuclei

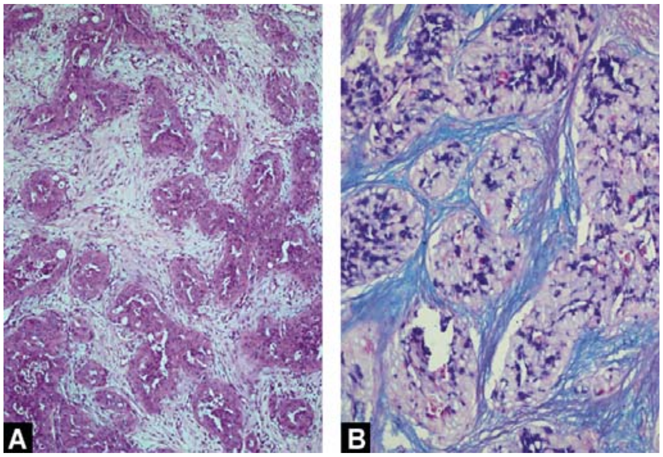

Figs 116.6A and B: Adenocarcinoma with A. Acinar pattern cells (H and E) showing mucin positivity, B. Alcian blue stain at pH 2.5

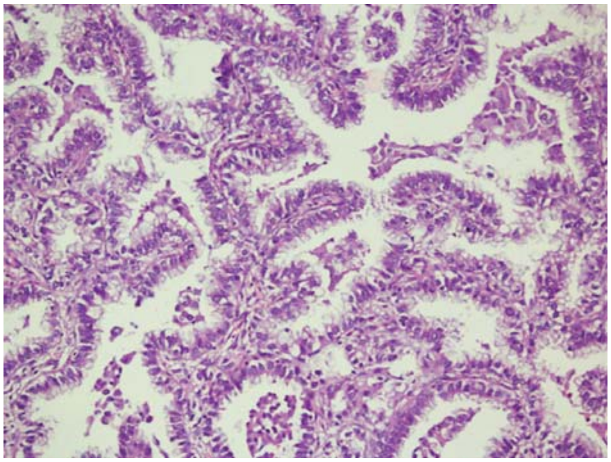

Fig. 116.7: Adenocarcinoma with extensive lepidic pattern of growth by mucinous cells

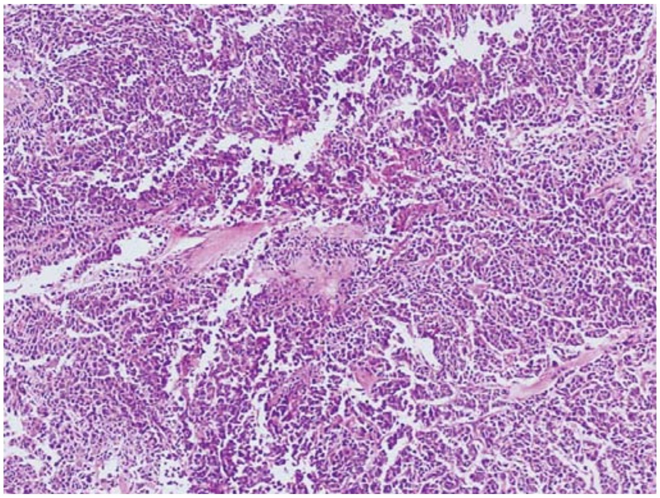

Fig. 116.8: Photomicrograph of small cell carcinoma with single cell infiltration, H and E

with stippled or ground glass chromatin. Only small indistinct nuclei are seen. There can be some larger cells with larger nuclei and occasional nuclei. Abundant cytoplasm may be seen. The0=se are intermediate sized small cell carcinomas according to older WHO classification (WHO 1973).

The small cell carcinoma cells show invariably membrane- bound, dense core neurosecretory granules. Immunohistochemically, cells express low molecular weight cytokeratin expression as perinuclear dot. The cells express neuroendocrine markers like neuron-specific enolase and synaptophysin or chromogranin. The small cell variant of squamous cell carcinoma and non-Hodgkin's lymphomas are the two differential diagnosis of small cell carcinoma. The finding of foci of keratinization will be useful for the diagnosis of basaloid squamous cell carcinoma.

Large Cell Carcinoma

The WHO classifies large cell carcinoma as a tumor of non-small cells with lack of light microscopic or histochemical evidence of glandular or squamous differentiation. This subtype is usually a collection of tumors. *In situ* changes are usually lacking. These tumors are usually peripherally located with pleural and chest wall invasion. Microscopically, the tumor usually shows cohesive clusters of large or intermediate polygonal cells, having abundant eosinophilic cytoplasm with large vesicular nuclei. There is always marked nuclear pleomorphism with numerous mitotic activity. The tumor cells do not show intercellular bridges or keratinizations which are characteristic of squamous cell carcinoma and devoid of any gland formation as seen in adenocarcinoma. A neutrophilic infiltrate is prominent in the stroma. There can be eosinophilic infiltrate (Figs 116.9 to 116.11). A diagnosis of large cell carcinoma hence requires a detailed sampling to exclude poorly differentiated squamous cell carcinoma or adenocarcinoma.

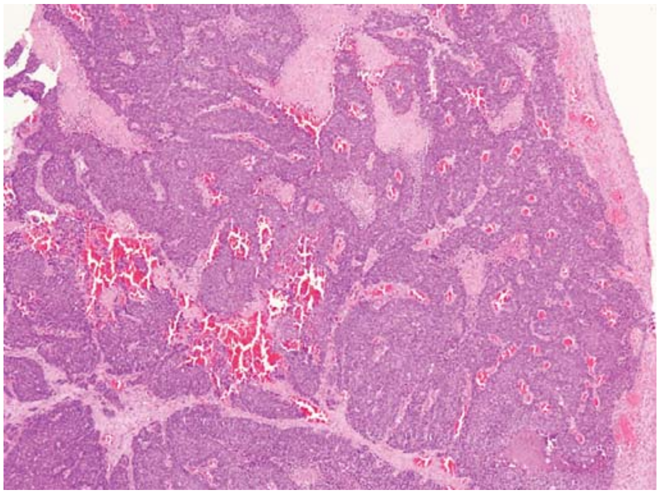

Fig. 116.9: Low power photomicrograph of large cell carcinoma showing large cluster of cells with areas of necrosis (H and E)

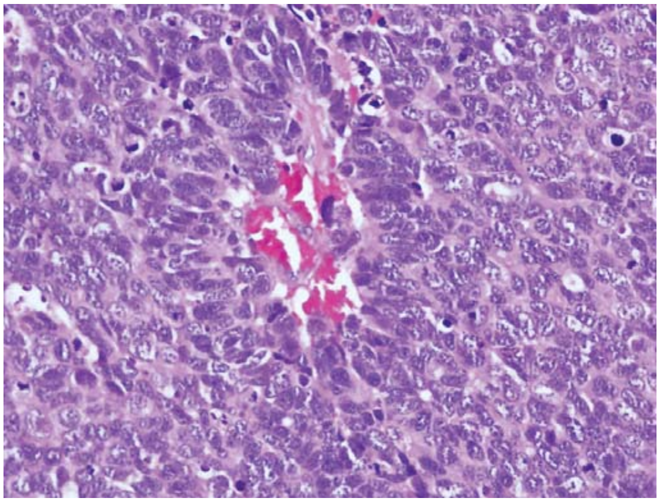

Fig. 116.10: High power photomicrography showing large pleomorphic cells without glandular or squamous differentiation (H and E)

Adenosquamous Carcinoma

The WHO defines a tumor as adenosquamous when both, i.e. adeno and squamous component are present in a same tumor with each occupying at least 10% of total tumorous area. The origin of tumor is mostly from pluripotent cells with dual differentiation. The collision

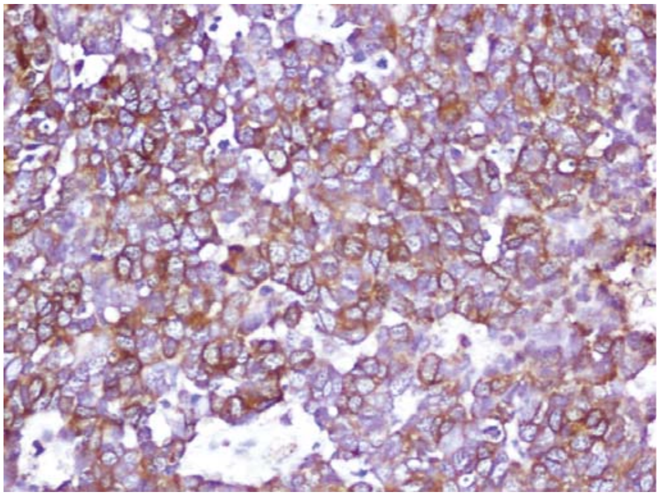

Fig. 116.11: Strong cytokeratin positivity in the neoplastic cells (MNF 116)

theory of adenocarcinoma and squamous cell carcinoma or squamous metaplasia of adenocarcinoma is unlikely.

NEUROENDOCRINE LESIONS OF LUNG[6,7]

A spectrum of neuroendocrine lesions is seen in the lungs:

Neuroendocrine Hyperplasia

- Neuroendocrine cell hyperplasia is seen in association with fibrosis and inflammation. Diffuse hyperplasia can be noticed with or without airway fibrosis or obstruction (Fig. 116.12). The periphery of carcinoid tumor may also show neuroendocrine hyperplasia (Figs 116.13 and 116.14).
- Among the pure neuroendocrine neoplasms, the conditions which are recognized are as follows: Tumorlets, typical carcinoid, atypical carcinoids, large cell neuroendocrine neoplasms and small cell carcinoma.
- A few non-small cell carcinomas can show neuroendocrine differentiation. Many other tumors are also neuroendocrine properties, e.g pulmonary blastoma,

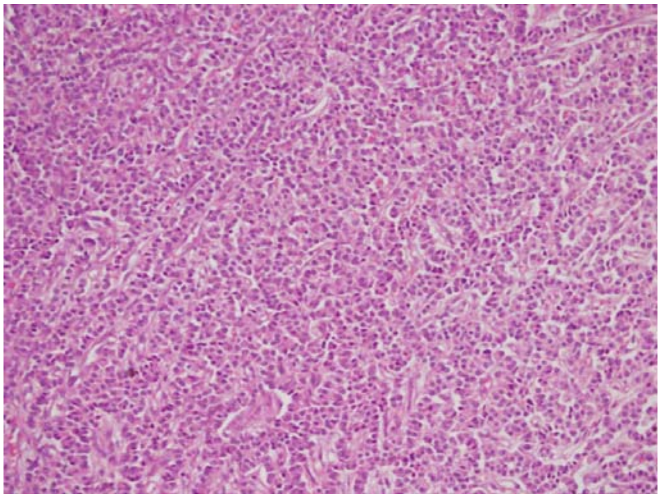

Fig. 116.12: Photomicrograph of carcinoid tumor with cluster of cells separated by thin vascular channels and gyriform pattern of growth (H and E)

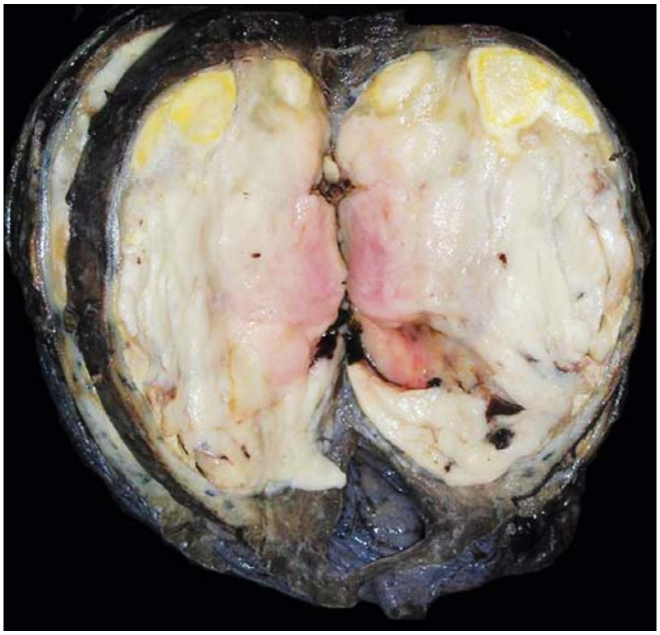

Fig. 116.13: Gross photograph of circumscribed carcinoid tumor

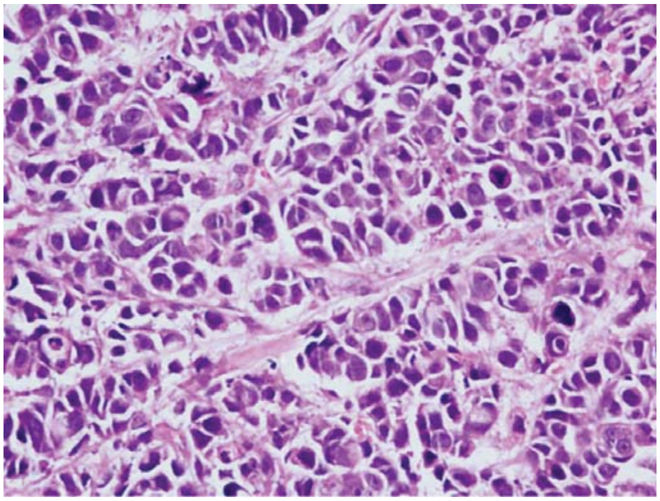

Fig. 116.14: High power photomicrograph showing nuclear molding (H and E)

primitive neuroendocrine tumors, desmoplastic round cell tumors, etc.

Tumorlets

Typical carcinoid tumor is characterized by a large yellow tan lesion in the central bronchus immediately beneath the surface epithelium. It can occur more proximally in the trachea or in the peripheral airways. It measures 0.5 cm or higher. The histological features show organized pattern with trabecular, insular, solid and spindle cell morphology. Other histological pattern like oncocytic, melanocytic pattern is also seen. The cells express neuron-specific enolase, synaptophysin and chromogranin A. The tumor show less than 2/10HPF (per 2 mm^2) mitotic figures without any areas of necrosis.

Atypical Carcinoid Tumor

These lesions are seen in the periphery of the lung in the majority of cases (60%). These are yellow-tan in color. Histologically, the tumor shows organoid pattern with prominent fibrous bands surrounding the groups of cells. The cells show more pleomorphism with increased mitotic figures and areas of necrosis. The mitotic figure is usually 2 to 10 mitoses per mm^2 (per 10 high power field).

Large Cell Neuroendocrine Carcinoma

These tumors are located peripherally and the tumor show cytological features of non-small cell carcinoma having neuroendocrine features like organoid, pallisading, rosettes or trabecular pattern. The cells are larger than three times of the nuclear diameter of resting lymphocytes. The tumors have high nuclear cytoplasmic ratio with increased mitotic rate (>10/10HPF) and areas of necrosis. Neuroendocrine markers, e.g. synaptophysin, chromogranin A and neuron specific enolase are usually positive in these tumors and show neurosecretory granules by electron microscopy.

Small Cell Carcinoma

The previous WHO classification divided this tumor into three types: oat cell type, intermediate cell type and combined oat cell carcinoma with squamous cell and adenocarcinoma. It has been observed that there were biological differences in the different subgroups. In 1999 WHO classification, the small cell carcinomas are dived into two subgroups:

a. Small cell carcinoma replacing the all other terminologies
b. Second group includes mixed small cell-large cell carcinoma and a combination of small cell carcinoma with neoplastic squamous or adenocarcinoma.

Small cell carcinomas are centrally located and the tumors are soft and gray white with areas of multifocal necrosis. The tumors frequently metastasize to different organs. The tumor cells have round to fusiform nuclei with fine strippled chromatin. Some cells are larger with occasional nucleoli. Nuclear material impregnation in the wall of vessels (Azzopardi phenomenon) is frequently seen with areas of necrosis. The tumors show low molecular weight cytokeratin positivity with expressions of neuron-specific enolase, synaptophysin or chromogranin.

Combined Small Cell/Large Cell Carcinoma

It is composed of small undifferentiated cells like small cell carcinoma along with scattered large cells within the small cells. The large cells show variable eosinophilic cytoplasm with distinct cell border and have large vesicular nuclei and prominent nucleoli.

Combined Small Cell/Non-small Cell Carcinoma

It is characterized by a tumor with characteristic small cell morphology combined with a squamous carcinoma, adenocarcinoma or large cell undifferentiated carcinoma component.

STAGING OF LUNG TUMORS[8-10]

An accurate staging of lung tumor is important for various reasons. It helps for collaboration and comparison of cases among various centers. It is extremely useful for treatment planning and evaluating the results of treatment; besides determination of prognosis.

Tumor Size (T Component)

It is an important prognostic indicator in the lung. The tumor diameters of 2 cm, 3 cm, 5 cm and 7 cm are taken into account. T1a is less than or equal to 2 cm but T1b denotes greater than 2 but less than or equal to 3 cm. The T2 is subdivided into T2a which is greater than 3 but less than or equal to 5 cm whilst the T2b is designated as greater than 5 but less than or equal to 7 cm. The T3 tumor is greater than 7 cm.

Two essential features are needed to discuss here:

1. *Measurement of tumor diameter*: The tumor should be measured before fixation. It is essential to subtract the adjacent region of pneumonia and

atelectasis. Regions of central scarring and necrosis should be taken within the measurement of tumor.

2. *Multinodularity of tumor*: In the 6th TNM staging system, the presence of additional nodules in the same lobe was classified as T4 and additional nodules in ipsilateral separate lobes were designated as M1 disease. The International Association for the Study of Lung Cancer (IASLC) recently published the Staging Manual in Thoracic oncology. In this new study, the tumors with multiple nodules (multinodular disease) within the same lobe showed similar survival pattern to T3 tumors, but ipsilateral multinodular disease in separate lobes showed survival pattern to T4 tumors. The histology is important in two areas. The first is to distinguish synchronous primary tumors from intrapulmonary metastases and the second is the changing from stage IV to stage IIIA in node negative disease. This allows the clinician to consider surgery as a primary treatment option even when tumors are considered intrapulmonary metastases.
3. *Differentiation of multiple primary tumors from metastases*[9]: The multiple nodules are usually metastatic. However, if the tumor nodules are histologically different; or when these nodules show a totally different component in different nodules; or these have different cytological or stromal features; or without any mediastinal lymph node metastasis or lymphatic emboli in common lymphatic drainage areas; then only these nodules can be labeled as multiple synchronous primary tumors. In case of multiple primary nodules, the T status should be given maximum with the number of nodules to be mentioned either as M or actual number like T(m) or T(3).
4. *Aspect of pleural invasion*[10]: The pleura is composed of several layers and from outer aspect to inner aspect, it consists of mesothelial layer, loose connective tissues, external elastic lamina, another layer of loose connective tissue and an ill-defined innermost internal elastic lamina. A definite pleural invasion means when a tumor crosses the external elastic layer and it can divided into:
   a. PL1; when it invades the elastic lamina
   b. PL2; when it invades the mesothelial surface
   c. PL3; when it invades the parietal pleura/chest wall. An elastic stain is always indicated for accurate assessment of pleural invasion. When a tumor invades the pleura at the interlobar fissure and it extends into the adjacent lobe, the staging remains T2.

N Component

N1 denotes when there is involvement of ipsilateral peribronchial, hilar and intrapulmonary lymph nodes. N2 is designated when subcarinal and ipsilateral mediastinal lymph nodes are involved. Supraclavicular, scalene and contralateral mediastinal lymph nodes are designated as N3.

M Component

When the tumor was confined to the lung, pleura and pericardium, it is labeled as M1a but with the discontinuous nodules in chest wall, diaphragm or mediastinal structures, it is designated as M1b. The distant metastases (outside of lung or pleura) are also designated as M1b. The ipsilateral separate nodules are down staged to T4 but the contralateral nodules are to be designated as M1a.

Lung Cancer: Clinical Manifestations

Javaid Ahmad Malik

INTRODUCTION

Lung cancer is usually recognized late in its natural history. In general, of newly presenting patients with lung cancer, 80% are inoperable at presentation and only 20% may proceed to curative resection.[1] The number of potentially resectable tumors at the time of diagnosis is much less in India. Lung cancer produces more symptoms in adults than any other cancer, which includes both respiratory and constitutional symptoms.[2-4] There is no clear demarcation between the clinical pictures of Small Cell Lung Cancer (SCLC) and Non-Small Cell Lung Cancer (NSCLC), however due to rapid dissemination of the disease, the duration of symptoms of small cell cancer tends to be shorter.

The symptoms and signs of bronchogenic carcinoma may be caused by any of the following: the local tumor itself, invasion of the tumor into the adjacent structures, regional lymph node enlargement, growth at anatomically discontiguous sites after dissemination and effects of tumor products leading to various paraneoplastic syndromes. Accordingly, the spectrum of clinical presentation of lung cancer can be divided into: (1) local manifestations, (2) metastatic manifestations and (3) nonmetastatic systemic manifestations (also called paraneoplastic syndromes). Most of the lung cancer patients in developing countries like India, compared to the patients in the developed countries, have lower mean age and advanced disease at diagnosis with 52% patients having evidence of metastases.[5-7]

LOCAL MANIFESTATIONS

Hemoptysis

Although the cardinal symptom of lung cancer particularly in an elderly smoker, hemoptysis, is neither the most common feature nor diagnostic of cancer. Hemoptysis is one specific symptom that prompts rapid consultation from the physician.[8] It is usually caused by bronchial mucosal ulceration, thus tends to be scanty. However, if the tumor erodes the bronchial artery or the pulmonary artery, as shown in Figure 117.1, hemoptysis

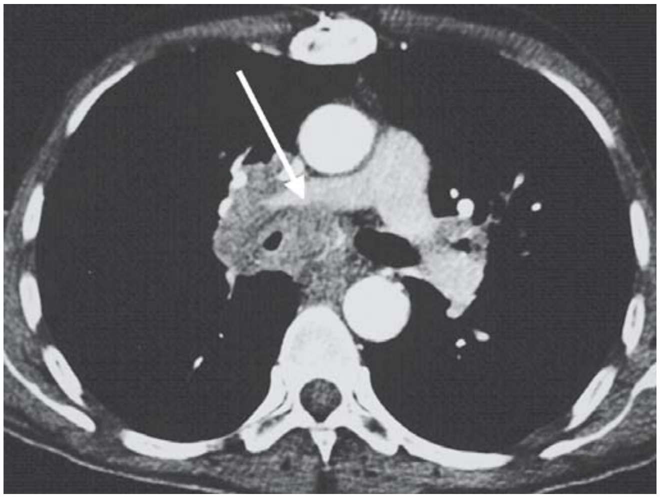

Fig. 117.1: Contrast computed tomography scan showing a large right hilar mass causing invasion and narrowing of the right pulmonary artery (arrow)

may be massive resulting in potentially fatal hemodynamic or airway compromise. Chest radiographs are usually abnormal in patients with hemoptysis, but in a small percentage of patients it may be normal.[9] In the developing countries like India, tuberculosis is always a competing diagnosis at all ages.

Cough

Cough is the most common presenting symptom of lung cancer, but it does not per se alarm the physician to look for malignancy, hence the delay in the diagnosis.[10,11] The development of new cough or a recent increase in the preexisting chronic productive cough in a middle aged smoker raises suspicion of lung cancer.[12] In smokers of more than 35 years of age, any new cough that persists for more than 2 weeks should be taken as suspicious of malignancy and investigated accordingly. Among the initial symptoms of lung cancer, cough is present in more than 65% patients and productive cough in more than 25% of patients and is more likely among patients with tumor originating in the airways.[13] In patients with chronic lung disease, a change in the character of an established cough may actually herald the development of lung cancer. Other conditions that can contribute to cough in these patients include esophageal reflux, coexisting Chronic Obstructive Pulmonary Disease (COPD) or congestive heart failure.[14]

Bronchorrhea, i.e. expectoration of large amounts of mucoid sputum occurs in 10% of patients with bronchioloalveolar carcinoma.[15] Endobronchial tumors cause cough either by airway obstruction and its associated postobstructive pneumonia or by bronchial mucosal ulceration, whereas peripheral tumors cause cough primarily by pleural involvement.

Breathlessness

- Like cough, dyspnea is the most commonly reported symptom in lung cancer, with 15% of patients having dyspnea at diagnosis and 65% at some point during the course of their illness.[16] In bronchogenic carcinoma, breathlessness is more common in men, older patients and those with lower quality of life scores and its incidence is higher when pain and anxiety predominate.[17,18] Various causes of dyspnea in patients with lung cancer includes:
- Direct involvement of the respiratory system by the tumor (major airway obstruction, consolidation, carcinomatous lymphangitis)
- Indirect respiratory complications of lung cancer (postobstructive pneumonia, pleural effusion, phrenic nerve paralysis)
- Treatment related (anemia or radiation and chemotherapy induced lung toxicity) respiratory complications that occur more frequently in these patients (pulmonary embolism and lung infections)
- Comorbid conditions (COPD, asthma, heart failure, prior lung resection, pericardial effusion and malnutrition). Some patients of lung cancer have no obvious cause of breathlessness but may have significant respiratory muscle weakness, due to general weight loss and the muscle deconditioning of advanced illness.[19]

Chest Pain

An ill-defined chest discomfort which is intermittent and aching in quality is common in bronchogenic carcinoma, occurs in up to 50% of patients at diagnosis. Definite pleuritic pain is the result of direct spread of the tumor to the pleural surface and is usually a manifestation of peripheral neoplasms (adenocarcinoma or large-cell carcinoma) because of their tendency to seed pleura. It is the invasion of pain receptors in the parietal pleura by the tumor that produces typical pleuritic pain which frequently disappears with accumulation of pleural fluid. Once the malignancy spreads beyond the pleura into the chest wall, it produces continuous pain that usually interferes with sleep. Shoulder pain that typically radiates along the ulnar distribution of arm may originate from local extension of tumor growing in the apex of the lung involving eighth cervical, and first and second thoracic nerves (Pancoast's or superior sulcus tumor).

METASTATIC MANIFESTATIONS

Intrathoracic Metastasis

Superior Vena Cava Syndrome

The thin vessel wall coupled with low intravascular pressure and surrounding lymph nodes, makes Superior Vena Cava (SVC) vulnerable to extrinsic compression and obstruction by the malignant tumor, leading to increased venous pressure in the head, neck and upper thorax producing a clinically unique entity known as Superior Vena Cava Syndrome (SVCS).[20,21] Bronchogenic carcinoma accounts for 46 to 75% of all cases of SVC obstruction, the most common histologi-cal subtype associated with SVCS is small cell carcinoma.[21-24] At the time of diagnosis, SVC obstruction is present in 10% of patients with SCLC and 1.7% with NSCLC.[25,26] Malignancies other than lung cancer that are responsible

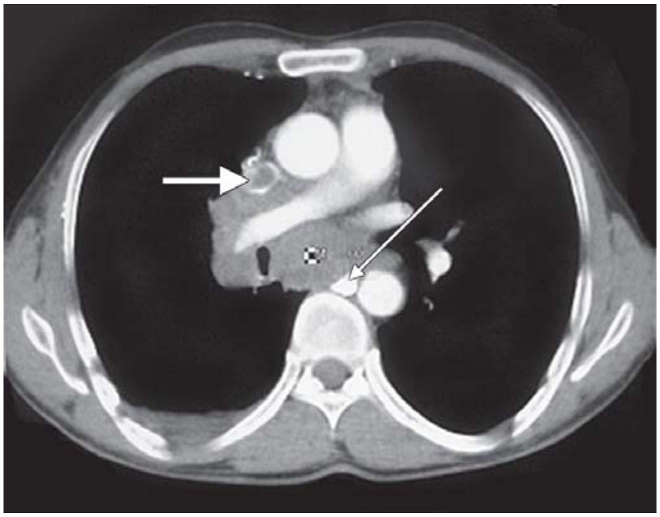

Fig. 117.2: Contrast CT scan chest of a patient of small cell carcinoma showing a thrombus in superior vena cava (short arrow). Enlargement of right hilar, sub-carinal and azygoesophageal recess lymph nodes is also seen. Note pleural effusion on right side and dilated azygos vein (long arrow) due to blood diversion

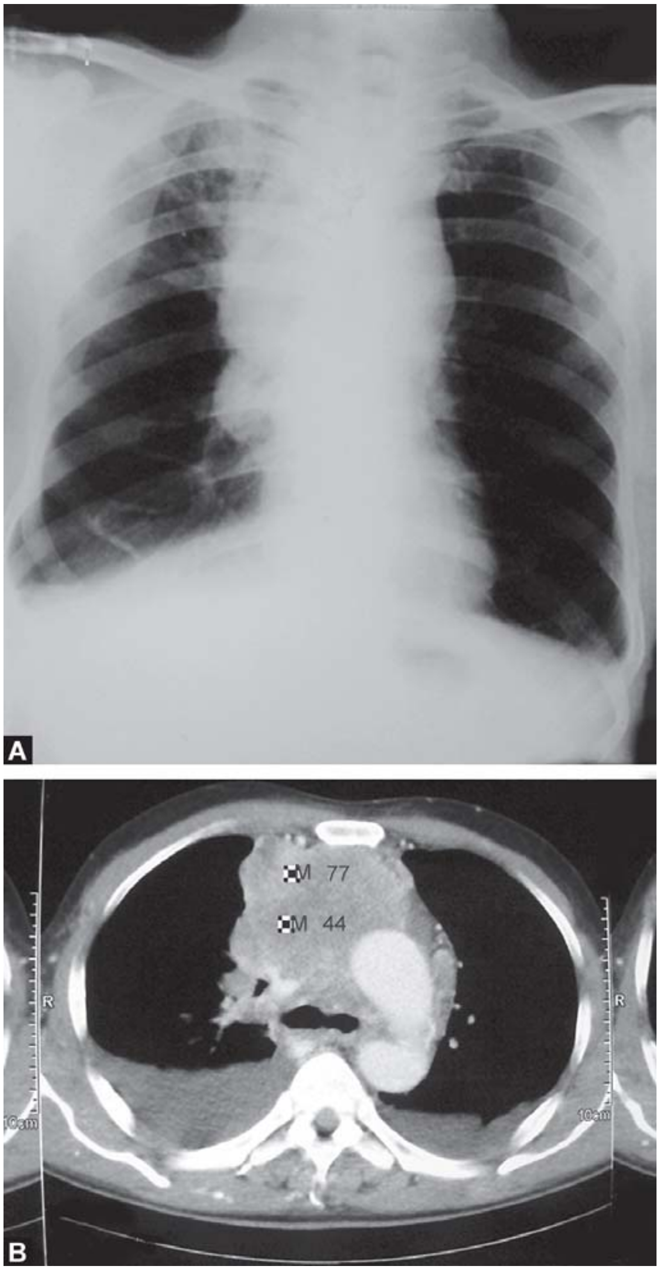
for obstruction of SVC in 20% of the cases include lymphoma, mesothelioma and metastatic mediastinal lymphadenopathy and the remaining 20% patients can have benign etiologies like granulomatous mediastinitis, mediastinal fibrosis, intrathoracic goiter or aneurysm, placement of pacemakers or thrombosis complicating central venous catheterization.[27-29] Various mechanisms that lead to SVC obstruction include direct compression by the primary tumor, compression by enlarged right paratracheal metastatic lymph nodes or intraluminal thrombosis (Fig. 117.2).

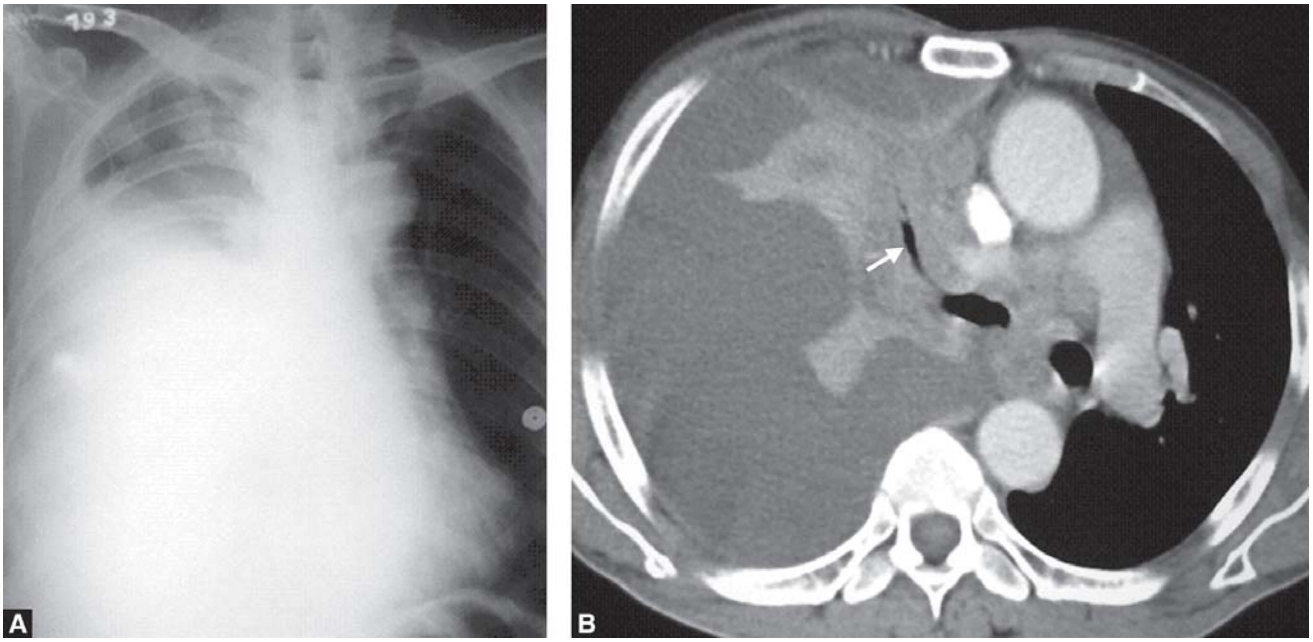
Symptoms of SVCS are often debilitating, tend to get exacerbated in supine position, include progressive swelling of neck, face, eyelids, arms and upper chest, conjunctival congestion, epistaxis, tinnitus, headache, disturbances in vision and sensorium.[20-23,30] Neck veins are distended and nonpulsatile, well developed collaterals are usually obvious on neck and anterior chest wall. SVC obstruction may get complicated with jugular venous and cerebrovascular thrombosis. Although radiograph of chest may show nonspecific mediastinal widening, diagnosis is usually confirmed by contrast CT scan (Figs 117.3A and B) which demonstrates not only the blockage of SVC with collateral formation but also suggests the most likely underlying etiology.

Malignant Pleural Effusion

Pleural effusions that occur due to direct pleural involvement by bronchogenic carcinoma occur in 7 to 15% of lung cancer patients.[31-33] On the other hand, paramalignant effusions are not the direct result of malignant involvement of the pleura but are still related to the primary lung tumor. Paramalignant pleural effusions may be due to postobstructive pneumonia



Figs 117.3A and B: Chest radiograph showing massive mediastinal adenopathy with right pleural effusion in superior vena caval obstruction in a 65-year-old male who presented with rapidly progressive swelling of neck, face and neck vein distension (A). Contrast CT scan showing a huge mediastinal mass causing posterior displacement and invasion of the aortic arch and SVC with bilateral pleural effusion. The diagnosis of small cell carcinoma was confirmed by bronchoscopic biopsy (B)



Figs 117.4A and B: Malignant pleural effusion. Chest X-ray (A) showing massive pleural effusion on right side. Contrast enhanced CT scan chest (B) showing massive pleural effusion causing compression of right upper lobe bronchus (arrow) and collapse of the underlying lung along with displacement of mediastinal structures to the left. Bronchoscopy in this 70-year-old male revealed an endobronchial growth and pleural fluid cytology confirmed metastatic non-small cell lung cancer

complicated by parapneumonic effusion, pulmonary embolism and infarction, chylothorax due to obstruction of the thoracic duct, radiation therapy and chemotherapy.[34,35] Lung cancer patients may also have pleural effusions that are due to concurrent non-malignant disorders like congestive heart failure, renal disease or hypoproteinemia.

Dyspnea, the most common presenting symptom of malignant pleural effusion is reported by more than 50% of patients.[35] Though, the exact mechanism of dyspnea in pleural effusions is unclear, various mechanical factors influencing the chest wall, depression of the ipsilateral diaphragm, mediastinum and its contents, pleural space, and the lung itself, all may contribute to dyspnea.[36-39] Malignant pleural effusion if massive (Figs 117.4A and B), may also produce other symptoms such as orthopnea, cough and chest discomfort.

Recurrent Laryngeal Nerve Palsy

Patients of lung cancer may develop hoarseness of voice because of vocal cord paralysis due to recurrent laryngeal nerve involvement. It produces cough that lacks explosive quality of a normal cough resulting in ineffectual expiratory noise (bovine cough). Recurrent laryngeal nerve palsy occurs in 2 to 18% of lung cancer patients, is associated with poor expectoration of tracheobronchial secretions and an increased risk of aspiration.[40] Left recurrent laryngeal nerve is more commonly involved due to entrapment by the tumor or by the metastatic mediastinal lymph nodes, as it passes over the left main bronchus and loops around the aortic arch. Right recurrent laryngeal nerve loops around right subclavian artery at the root of neck and may be involved by thoracic inlet tumor or metastatic cervical nodes.

Phrenic Nerve Paralysis

Diaphragmatic paralysis may complicate lung cancer due to phrenic nerve entrapment by the tumor in the mediastinum.[40] In unilateral phrenic nerve dysfunction, patient may not have any specific symptom, it may be incidentally discovered on the chest radiograph from the presence of an elevated hemidiaphragm. In bilateral phrenic nerve paralysis, patients are severely symptomatic, have orthopnea and a downhill disease course.

Pancoast's Syndrome

Pancoast tumor (also known as thoracic inlet or superior sulcus tumor) is a complication of local extension of an apical lung cancer. It was first reported in 1924 by Henry Pancoast, a radiologist from the University of Pennsylvania.[41] It is usually associated with squamous cell lung cancer, however any histological type of bronchogenic carcinoma can produce this syndrome. Pancoast tumors are uncommon, comprise fewer than 5% of all lung cancers.[42] The syndrome results from the involvement of lower part of brachial plexus by the tumor producing pain in the lower part of shoulder and inner aspect of arm along C8, T1 and T2 distribution that may be associated with sensory loss, weakness and wasting of the small muscles of hand. Incomplete forms of the Pancoast's syndrome are also seen in clinical practice. Radiologically, in addition to the apical lung mass, Pancoast tumor is often characterized by the destruction of first and second ribs posteriorly and sometimes of transverse process or vertebral body. In anterior superior sulcus tumor, the predominant complaint is chest pain; the imaging studies reveal destruction of anterior ends of first and second ribs and invasion of subclavian vessels. In order to determine the extent of involvement of neurovascular structures, a Magnetic Resonance Imaging (MRI) scan is often required in addition to a CT scan in the evaluation of Pancoast tumor.

Horner's Syndrome

Horner's syndrome is a consequence of invasion by the apical lung cancer of the lower cervical and first thoracic ganglia, which frequently fuse into a single ganglion, the stellate ganglion. It may be observed in 20 to 50% of bronchogenic carcinoma patients at presentation.[43] Its clinical components include ipsilateral ptosis, miosis, enopthalmos and lack of facial sweating (anhidrosis). Application of topical cocaine to the miotic eye fails to cause pupillary dilatation, while appropriate dilatation is noted in the unaffected eye.[44] Horner's syndrome is usually a complication of superior sulcus lung tumor, but may very rarely complicate spontaneous pneumothorax that produces mediastinal shift and consequent mechanical traction of the sympathetic ganglion.[45,46]

Involvement of Heart and Pericardium

Cardiac and pericardial metastases from bronchogenic carcinoma usually occur by direct lymphatic spread. In lung cancer, cardiac involvement is reported in 15% of the cases at autopsy.[47] Pericardium is the most common site of cardiac involvement in lung cancer (Fig. 117.5). Some patients may even develop cardiac tamponade.[48]

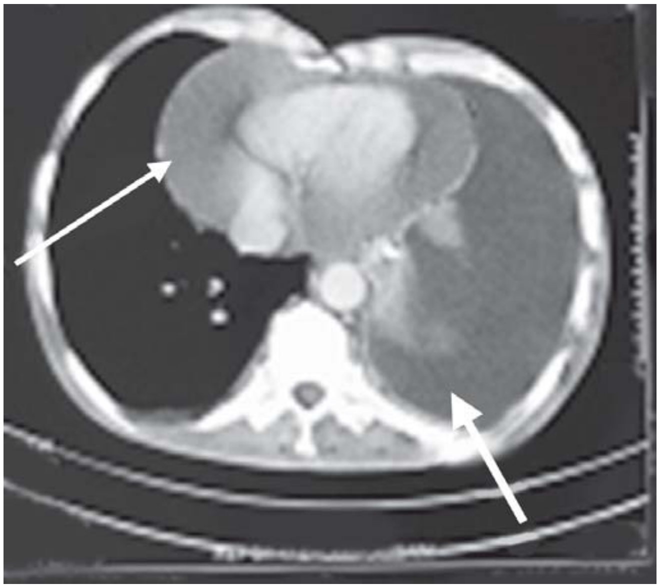


Fig. 117.5: Malignant pericardial effusion. Sixty-five years old male patient had signs of pleural effusion and volume loss on left hemithorax. Contrast CT scan chest showing pericardial effusion (long thin arrow) and volume loss on left side with massive pleural effusion (short thick arrow) on the same side. Bronchoscopy revealed an endobronchial growth that completely occluded the left main bronchus. Patient subsequently developed cardiac tamponade that needed pericardial catheter drainage

Involvement of Esophagus

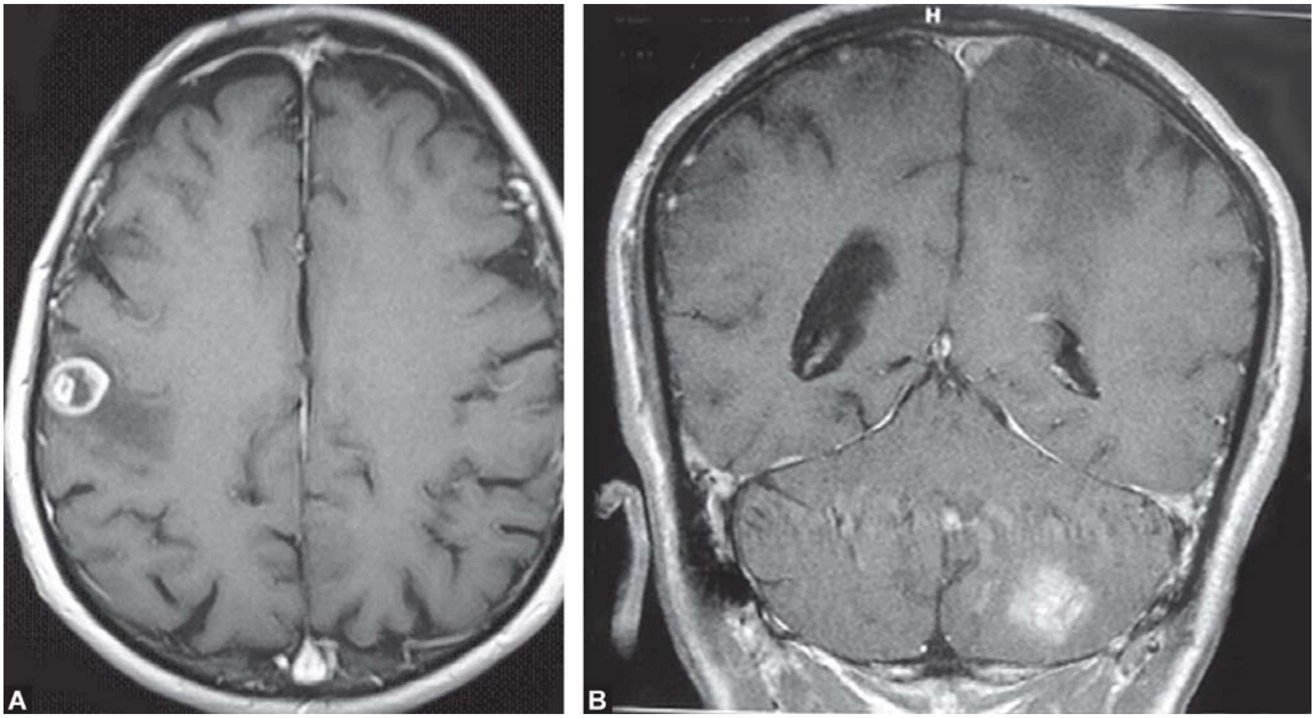
Dysphagia due to esophageal compression by massively enlarged metastatic hilar and mediastinal nodes is an unusual clinical feature of lung cancer and is generally a late symptom.

Extrathoracic Metastasis

Metastases from lung cancer may occur in virtually every organ system but are more commonly in brain, bones, liver, adrenal glands and lymph nodes. Extrathoracic spread of bronchogenic carcinoma makes a patient clearly inoperable. Metastatic disease in general, is more common with small cell than with non-small cell lung cancer.

Brain Metastases

Intracranial metastases constitute the first clinical problem in 10% of SCLC patients the cumulative incidence at 2 years is more than 50%.[49] Likewise, brain metastases from NSCLC occur in 33% of patients.[50] It is more common from lung cancer than from any other primary site, lung being the primary site of 70% of



Figs 117.6A and B: Brain metastasis from bronchogenic carcinoma. (A) Post-Gadolinium T1-W MRI of the brain in a patient of small cell carcinoma lung showing a ring enhancing lesion with a central nodule and thick walls surrounded by vasogenic edema in the right parietal lobe. (B) Coronal Post-Gad MRI in a 55-year-old male patient showing metastatic deposits in the cerebellum with avid enhancement of the lesion (*Courtesy:* Dr Irfan Rubani, Radiologist, SKIMS)

cancers that initially present with symptomatic brain metastases.[51] Squamous cell lung cancer metastasizes to brain less often than adenocarcinoma and large cell carcinomas.[52] Sometimes, brain metastases form the only extrathoracic site of spread of lung cancer.[53]

Intracranial metastatic lung cancer usually presents with headache, nausea and vomiting, rarely with impaired intellectual function or personality changes. Seizures and motor or sensory neurological deficits may occur. Progressive neurological symptoms in cerebral metastases usually complicate the widespread disease. Rarely, brain metastases are detected when primary bronchogenic carcinoma is asymptomatic and radiological examination of the chest is normal. If the patient with brain metastases is not treated, neurologic deterioration occurs quickly.[54,55] Lung cancer can metastasize to any part of the brain (Figs 117.6A and B) and cause devastating neurological complications.

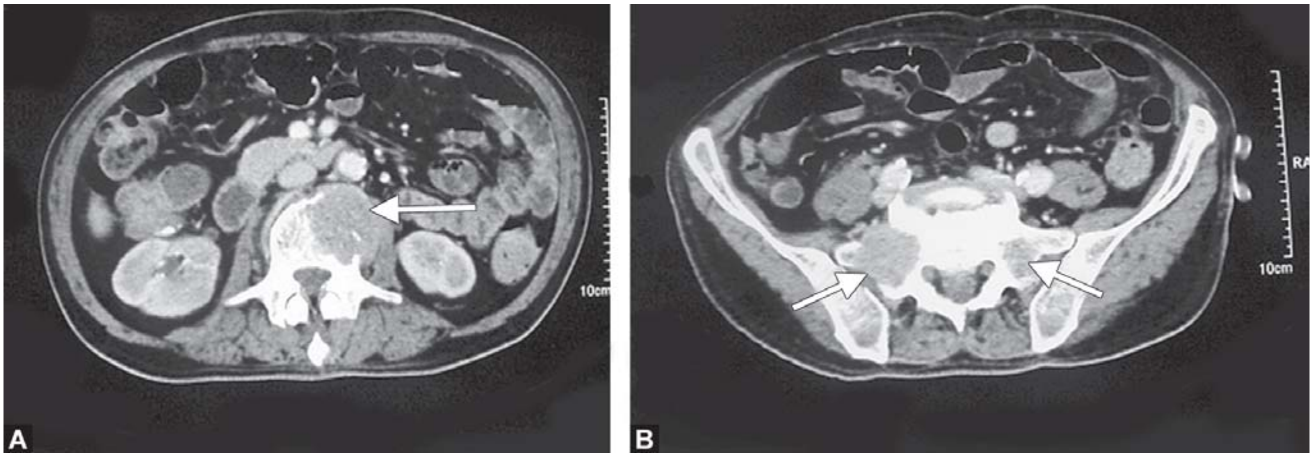
Skeletal Metastases

Bronchogenic carcinoma frequently metastasizes to vertebrae (Figs 117.7A and B) and ribs however, any bone in the body may be involved. Bony metastases usually produce pain which is invariably progressive. If the ribs are involved, pain gets aggravated by coughing and body movement.[56] Skeletal metastases may also lead to pathological fractures. When bone marrow is invaded by metastatic lung cancer, it leads to cytopenias or leukoerythroblastosis.

Radiograph of the affected bone may reveal lytic lesion, but it is not as sensitive as isotope bone scanning in detecting skeletal metastases. Though sensitive, bone scan lacks specificity, up to 50% of the scans may be false-positive, mostly due to benign metabolic bone disorders.[57,58] Bone scan is more useful in small cell carcinoma, because of the higher incidence of skeletal metastases with SCLC than with NSCLC.[59] Rarely, bone biopsy is required to confirm the metastatic spread of bronchial tumor.

Spinal Cord Compression

Due to epidural or vertebral metastases may complicate lung cancer producing an oncologic emergency.[60] Such patients need immediate assessment by a neurologist. Spinal cord metastases are less common and tend to occur in patients with cerebral metastases.



Figs 117.7A and B: Spinal metastasis from bronchogenic carcinoma. CT scan showing lumbar vertebral body deposits (A) and multiple sacral deposits (B) [*Courtesy:* Dr Syed Nisar, SKIMS Hospital]

Adrenal Metastases

Involvement of adrenal glands (Fig. 117.8) by metastatic lung cancer, usually by small cell carcinoma, is common but rarely produces adrenal insufficiency.[40] Solitary adrenal metastasis if resected along with primary lung tumor has a better prognosis with a 3-year survival rate of 38%.[61] Surgical resection for solitary adrenal metastases, in comparison to chemotherapy alone for usual disseminated metastatic disease, prolongs the median survival, resulting in survival rate of 17% at 15 years.[62]

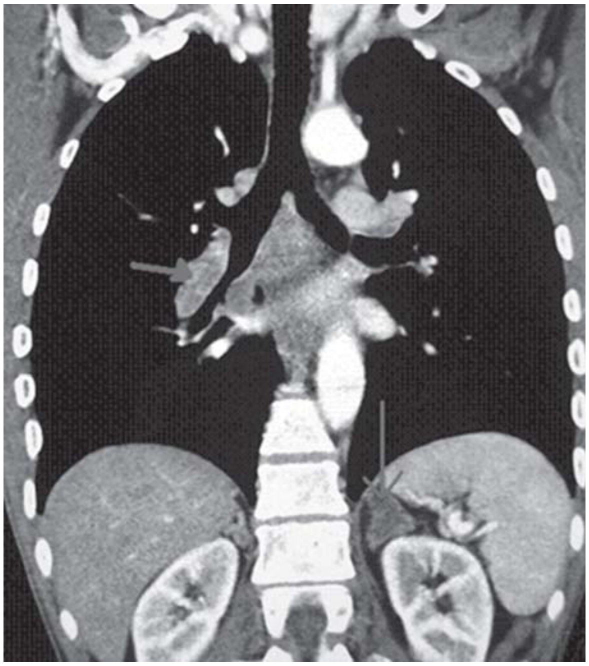


Fig. 117.8: Coronal contrast CT scan revealing a right hilar bronchogenic carcinoma (short thick arrow) with metastasis in the left adrenal gland (long thin arrow)

Lymph Node Metastases

An enlarged lymph node due to metastatic lung cancer is extremely helpful in facilitating both diagnosis and staging. Supraclavicular lymph nodes are the more common sites of palpable lymphadenopathy in lung cancer, involved in 15 to 20% of patients during the course of the disease.[40] Fine needle aspiration of the enlarged lymph node has high sensitivity and little morbidity.[63]

Hepatic Metastases

Liver metastases occur commonly with lung cancer (Fig. 117.9), their presence carries a very poor prognosis.[40] Patient usually complains of fatigue and weight loss; on physical examination the liver is hard and irregularly enlarged. However, liver function test results are seldom abnormal until the metastases are numerous and large. Both ultrasonography and CT scan are equally good in picking up hepatic metastases, a finding that makes the patient inoperable.[64]

Paraneoplastic Syndromes

A group of clinical disorders that are associated with malignant diseases, not directly related to the physical effects of primary or metastatic tumors are known as paraneoplastic syndromes.[65] These syndromes occur in 10% of patients with lung cancer.[66,67] The pathogenetic mechanisms by which paraneoplastic syndromes occur are not fully understood in all cases, but in many it

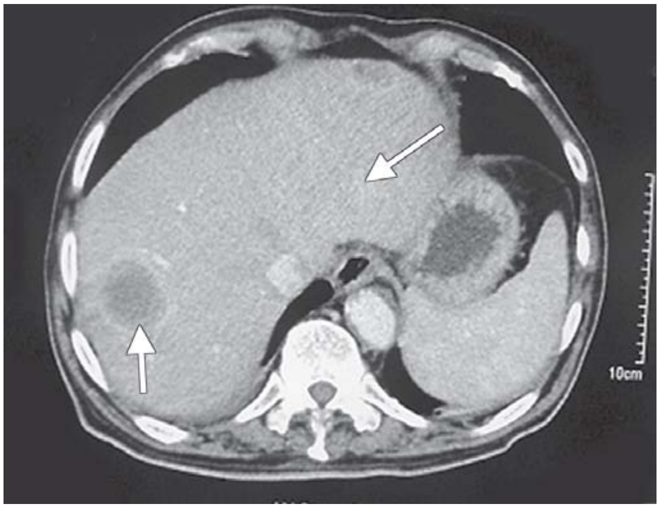

Fig. 117.9: Hepatic metastasis in lung cancer. Contrast CT scan of a 65-year-old male with small cell carcinoma of lung shows multiple ring enhancing lesions in liver (arrows). These lesions on FNAC were found to be metastatic deposits

appears to relate with either the production of biologically active substances by the tumor itself (e.g. polypeptide hormones or cytokines) or in response to the tumor (e.g. antibodies).[68] The size of the primary tumor has no impact on the extent of paraneoplastic symptoms. These paraneoplastic syndromes can precede the diagnosis of malignant disease, may occur late in the course of the illness or herald the first sign of recurrence of lung cancer. The most common tumors producing paraneoplastic syndromes in humans are lung cancers. Paraneoplastic syndromes are more frequently associated with small cell cancers but can be seen with any histological type. These unique clinical entities may antedate the discovery of tumor by months, or even years.[69] Paraneoplastic syndromes may simulate metastatic cancer thereby leading to inappropriate palliation rather than curative treatment of the underlying tumor. With successful treatment of lung cancer, the paraneoplastic phenomena usually resolve.

ENDOCRINE SYNDROMES

Cushing's Syndrome

Lung cancer is the most common source of ectopic secretion of Adrenocorticotropic Hormone (ACTH) among nonpituitary neoplasms. Biologically active ACTH resulting in adrenal gland hyperplasia and hyperfunction is usually produced by small cell carcinoma (85%), uncommonly by carcinoid tumors (10%) and adenocarcinoma (5%) of the lung. Lung cancer cells express precursor gene, Pro-opiomelanocortin (POMC) from which ACTH is derived. Increased serum levels of ACTH may be detectable in up to 50% of patients with bronchogenic carcinoma.[70] Cushing syndrome has been described in 1 to 5% of patients with SCLC.[71,72] Paraneoplastic Cushing's syndrome may rarely be caused by ectopic production of Corticotropin Releasing Hormone (CRH) which leads to excessive ACTH secretion from the pituitary gland.

Because of the short natural history of small cell lung cancer, these patients usually do not develop the classical features of Cushing's syndrome like buffalo hump, moon facies or cutaneous striae, as seen in Cushing's disease due to pituitary adenoma. Diagnosis is usually suggested by features of acute hypercortisolism such as hypertension, hyperglycemia and hypokalemic alkalosis. Muscle weakness associated with hypokalemia, may be profound. Proximal myopathy and edema are commonly found on physical examination.[73] However, full-blown Cushing's syndrome may be caused by certain slow growing cancers like pulmonary carcinoids and tumorlets.[74,75] Clinical course of Cushing's syndrome may be complicated by devastating fungal infections.

Though the biochemical abnormalities of cortisol metabolism including the raised ACTH levels, loss of diurnal variation and failure of cortisol levels to suppress after dexamethasone administration are found in 50% patient's with SCLC, the clinical syndrome is obvious in less than 5%.[68,76,77] Diagnosis is confirmed by demonstration of plasma ACTH level of more than 22 pmol/l, plasma cortisol of more than 600 nmol/l and 24-hour urinary free cortisol of more than 400 nmol/day, which do not suppress after a high-dose dexamethasone.

In addition to the effective treatment of the underlying lung malignancy, hypercortisolism needs to be addressed early to reduce the morbidity. Chemotherapy with or without irradiation for small cell carcinoma and surgical resection for carcinoid tumors should be offered to the patient as early as possible. When the tumor cannot be resected or ectopic ACTH secretion cannot be controlled, bilateral adrenalectomy may be effective in some patients.[78] Ketoconazole, metapyrone, aminoglutethimide or octreotide may be used to induce effective steroid synthesis inhibition.[79] Ectopic ACTH production by small cell carcinoma of lung is associated with aggressive tumor behavior, hence poor prognosis.[76]

Hypercalcemia

Overall, 10% patients of lung cancer have hypercalcemia, which usually complicates squamous cell carcinoma that secretes parathyroid hormone-related peptide (PTH-rP).[80-82] Hypercalcemia may also be seen with adenocarcinoma, but it is extremely rare in patients with small cell carcinoma of lung. Although bone metastases may be found in patients with lung cancer and hypercalcemia most commonly humoral mechanisms account for the hypercalcemia.[83,84] Bronchogenic carcinoma causes hypercalcemia primarily by ectopic production of parathyroid hormone-related peptide (PTH-rP), uncommonly by osteolytic metastatic deposits and very rarely by ectopic secretion of Parathyroid Hormone (PTH).[83-85] PTH-rP and PTH share identical functional activity because the first eight amino acids are homologous in these two peptide hormones. PTH-rP binds to PTH receptors in the bone and the kidney causing enhanced osteoclastic bone resorption and decreased urinary calcium excretion.

The diagnosis of PTH-rP associated paraneoplastic syndrome is considered if serum calcium level exceeds 10.5 mg/dl. Hypercalcemia initially produces nausea, vomiting, constipation, polyuria and nocturia resulting in hypovolemia and renal failure. As serum calcium goes up, patient may become confused, and drowsy and ultimately, coma may supervene misleading the physician towards intracranial metastases. The clinical behavior of PTH-rP associated paraneoplastic syndrome is highly unpredictable, the patient may present with subtle symptoms or as medical emergency. Increased levels of urinary cyclic adenosine monophosphate have been reported in lung cancer patients consistent with increased PTH effect.[86] However, serum immuno-reactive PTH levels are low to undetectable.[87] A protein with PTH-like activity has been purified from lung cancer cell lines.[88,89] Bone scan should be obtained to exclude skeletal metastases. An elevated PTH-rP level confirms the diagnosis in the absence of bone metastases. Other causes of hypercalcemia like sarcoidosis, hyperthyroidism and drugs like thiazides, lithium and vitamin D should also be considered in the differential diagnosis. Primary hyperparathyroidism should be excluded by PTH radioimmunoassay.

PTH-rP associated hypercalcemia usually develops in patients with advanced lung cancer, treatment may not be always required. Control or treatment of underlying lung cancer constitutes the most effective method of managing hypercalcemia. Intravenous saline, usually with furosemide diuresis, is often sufficient in symptomatic mild to moderate hypercalcemia. In severe hypercalcemia, calcitonin is used because of its rapid onset of action. Biphosphonates are used for long-term control of hypercalcemia and may cause dramatic fall in serum calcium.[90] Glucocorticoids though frequently used, have an unreliable calcium lowering effect in this syndrome. Similarly, mithramycin, a cytotoxic antibiotic is rarely used because of its toxicity.

Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

Elevated Antidiuretic Hormone (ADH) levels and impaired water handling are found in 30 to 70% of patients with lung cancer, but the production of excess ADH does not always produce symptoms.[91-93] Only 1 to 5% of lung cancer patients have symptoms that are attributable to the SIADH production. The SIADH production is mainly associated with small cell lung cancer, although other malignant tumors of the lung may rarely be associated with this syndrome.[91,94-96] The excess levels of ADH have been reported to originate from either ectopic production by lung cancer cells or inappropriate peripheral baroreceptor stimulation of ADH release from the hypothalamus.[91,97] Excess of ADH leads to abnormal water retention resulting in hyponatremia and low plasma osmolality. Urinary loss of sodium continues at a level inappropriate for plasma sodium concentration resulting in urinary osmolality twice as high as concomitant plasma osmolality. In a patient of lung carcinoma with euvolemic hypoosmolar hyponatremia, diagnosis of SIADH is made by the measurement of plasma and urinary osmolality.

The exact role of Atrial Natriuretic Peptide (ANP) in hyponatremia of malignancy is not known, though it is also ectopically secreted by the lung tumors. ANP also affects renal salt and water handling. In an individual patient, increased levels of ANP may contribute to hyponatremia by inducing natriuresis.[97] If plasma sodium concentration is marginally low, patient may be asymptomatic or may have confusion, headache, nausea and vomiting. Sodium level of less than 115 mmol/L can produce convulsions, coma and death. However, more often than not, lung cancer associated hyponatremia is only a laboratory abnormality.

Like for any other paraneoplastic phenomenon, the treatment of SIADH consists that of the underlying tumor. The syndrome resolves within 3 weeks after the initiation of combination cytotoxic chemotherapy in 80% of SCLC patients, but commonly recurs with tumor progression.[98] Though the chemotherapy of small cell carcinoma usually results in prompt resolution of SIADH[99] however clinician should keep in mind that some of the drugs like cisplatin, vincristine, melphalan and cyclophosphamide used to treat these cancers can themselves produce SIADH.[100]

Other measures which may be effective to counter hyponatremia while awaiting the effects of chemotherapy include strict fluid restriction (i.e. 500 ml per day), which alone may be sufficient to maintain serum sodium above 128 mEq/L.[101] If patient does not comply with fluid restriction or if it does not prove effective, demeclocycline, which blocks the action of vasopressin in the renal tubule, is used in a daily oral dose of 600 to 1200 mg.[102,103] Severe symptomatic hyponatremia is treated with hypertonic saline (3%) along with intravenous loop diuretic that enhance net free-water clearance. Sodium level should not be raised by more than 2 mEq per hour because it may lead to central pontine myelinolysis, an acute neurologic catastrophe. Unlike ectopic ACTH hormone production, SIADH does not worsen the prognosis of small cell cancer.

Acromegaly

Carcinoid tumor is the most common cause of acromegaly associated with lung malignancy. Small cell carcinoma can also produce this syndrome. Paraneoplastic acromegaly is commonly caused by secretion of Growth Hormone-Releasing Hormone (GHRH) and rarely by Growth Hormone (GH) in to the blood. These patients develop thick leathery skin, prominent skin folds, hypertrophy of face and extremities and sometimes diabetes and hypertension. Increased plasma levels of GHRH and insulin like growth factor-1 (IGF-1) in the presence of a lung tumor, virtually establish the diagnosis. Lung cancer related acromegaly promptly responds to surgical resection as well as to radiotherapy. Patients, who are not eligible for resection or irradiation, should receive octreotide, which inhibits GHRH secretion from the tumor and decreases GH and IGF-1 levels in the serum.

NEUROLOGICAL SYNDROMES

In patients of bronchogenic carcinoma, a variety of poorly understood neurological syndromes including Lambert-Eaton Myasthenic Syndrome (LEMS), limbic encephalopathy, polyneuropathy, cerebellar degeneration, retinopathy, opsoclonus-myoclonus and autonomic neuropathy have been reported.[104-107] Paraneoplastic neurologic syndromes affect 5% of lung cancer patients, associated almost exclusively with small cell carcinoma.[105] The severity of neurologic symptoms is unrelated to the tumor bulk; more often seen in patients with limited disease, in some patients a primary malignant lesion may be undetected before death despite the disabling symptoms.[106,108-110] The syndromes develop through autoimmune mechanisms as nearly all are associated with the presence of type 1 antineuronal nuclear antibodies (also known as anti-Hu antibodies).[111] Upto 20% of patients with small cell lung cancer have detectable circulating levels of anti-Hu antibodies but paraneoplastic neurologic syndromes may not develop in all of these patients.[106,112]

The diagnosis of a neurologic syndrome should be made only after other causes such as electrolyte imbalance, metastatic disease, cerebral and spinal vascular disease, infections and treatment toxicity are carefully excluded. These neurological phenomena progress rapidly and cause significant disability. The response of the neurologic syndrome to an effective chemotherapy in patients with small cell cancer is variable.[73,113-115] Sustained improvements particularly in patients with motor or sensory neuropathies have been reported. The overall prognosis is more favorable in SCLC patients with LEMS than in those without it.[116, 117]

Eaton-Lambert Syndrome

Eaton-Lambert myasthenic syndrome affects up to 5% of patients with small cell lung cancer uncommonly complicates non-small cell lung cancer. It is caused by the formation of IgG autoantibodies directed at voltage-gated P/Q calcium channels involved in the release of acetylcholine at nerve terminals thereby producing a functional blockade at neuromuscular junction.[73,118]

These patients usually present with fatigue, dysphagia, dysarthria, visual blurring, muscle aches and weakness of pelvic girdle muscles. Unlike in myasthenia gravis, muscle weakness in LEMS improves with exercise and not with anticholinestrases. The syndrome is worse in the morning and improves during the day. Although, extraocular muscle involvement is uncommon ptosis is often seen.[119] There is increased muscle action potential with repeated nerve stimulation on electromyography. Demonstration of IgG autoantibodies in the serum of patients with small cell lung cancer confirms the diagnosis of Eaton-Lambert syndrome.

Eaton-Lambert syndrome usually resolves with chemotherapy of small cell carcinoma. If treatment of lung tumor does not improve neuromuscular weakness, remission may be induced with azathioprine, intravenous gamma globulin, diaminopyridine or plasma exchange.

Encephalomyelitis and Sensory Neuropathy

This syndrome is associated with small cell lung cancer and the neuronal damage is mediated by IgG anti-Hu antibody, also known as Anti-Neuronal Nuclear Antibody (ANNA-1).[120] The anti-Hu antibody, present in the blood of these patients, reacts with proteins on small cell carcinoma cells and also with neuronal nuclear antigens in the brainstem, cerebellum, cerebral cortex, spinal cord and dorsal root ganglia.[121]

These patients may present with progressive sensory loss in hands and feet, myelopathy, brainstem involvement or features of limbic encephalopathy including behavioral changes, memory loss or convulsions. Autonomic neuropathy resulting in postural hypotension or gastrointestinal motility disturbances may also occur.[122] Diagnosis of encephalomyelitis is suggested by the MRI images which show increased T2 signal in the affected areas of the brain and is confirmed by demonstration of anti-Hu antibody in the serum.

Removal of culprit IgG by plasmapheresis and corticosteroids administration is effective in only 15% of these patients.

Paraneoplastic Cerebellar Degeneration

Some patients of small cell lung cancer develop cerebellar degeneration leading to nystagmus, impaired coordination and ataxia.[123] These patients have anti-Hu antibodies in serum and frequently tend to develop encephalitis or sensory neuropathy.

Cancer Associated Retinopathy

It is a rare paraneoplastic syndrome that occurs as the first sign of occult small cell carcinoma of lung. Ganglion cells of retina are characteristically damaged by binding of auto-antibodies to recoverin, a photoreceptor-specific protein. Clinically, these patients have photosensitivity, rapid loss of vision, night blindness, visual field defects and arteriolar narrowing. In a given clinical setting, demonstration of anti-recoverin antibody establishes the diagnosis of cancer associated retinopathy. Cancer associated retinopathy responds to systemic steroids but not to the chemotherapy for primary tumor.

Opsoclonus and Myoclonus

This rare paraneoplastic syndrome is associated with both small cell and non-small cell lung cancers. The patient shows rapid involuntary conjugate eye movements in both the horizontal and the vertical directions. Some SCLC patients with this syndrome have anti-Hu antibody in serum.

HEMATOLOGICAL SYNDROMES

Granulocytosis

Granulocytosis with absolute white cell count of 10,000 to 25,000 occurs in 20% patients of non-small cell lung cancer. The specific ectopic hormone responsible for paraneoplastic granulocytosis has not been characterized, although some non-small cell tumors may produce various cytokines like Interleukin-6 (IL-6), granulocyte colony-stimulating factor (G-CSF) or granulocyte-monocyte colony-stimulating factor (GM-CSF). The increase in total white cell count may also be associated with neutrophilia and eosinophilia.[124,125] Bone marrow biopsy is usually normal. Diagnosis is made on exclusion, granulocytosis per se does not produce any symptom in these patients.

Thrombocytosis

Paraneoplastic thrombocytosis is a common phenomenon observed in 40% patients of both small cell and non-small cell carcinomas. The exact pathogenetic mechanism of lung cancer associated thrombocytosis is not known, it is most likely linked to a megakaryocyte cytokine, i.e. IL-6. Like granulocytosis, lung cancer associated thrombocytosis is asymptomatic, diagnosed if bone marrow biopsy is normal and platelet count exceeds 500,000/mm.[2]

Thromboembolism

The pathogenetic basis of lung cancer associated venous thromboembolism is not known, no proteins or cytokines have been linked to it. It can complicate both non-small cell and small cell cancers of lung. Trousseau's syndrome or recurrent migratory venous thrombophlebitis is more commonly associated with bronchogenic carcinoma than pancreatic or other gastrointestinal cancers. Isolated venous thrombosis is treated with oral warfarin, but long term heparin is more effective than warfarin in recurrent thrombosis (Trousseau's syndrome).[126]

SKELETAL

Digital Clubbing and Hypertrophic Osteoarthropathy

Digital clubbing (Fig. 117.10) which is, more common among wowen than man (40 vs 19%), is observed in more than 30% patients and Hypertrophic Pulmonary Osteoarthropathy (HPOA) in up to 10% patients of non-small cell lung cancer, more common among women than men (40% vs 19%).[127,128] Quantitative indexes of the nail profile angle, hyponychial angle and phalangeal depth ratio can be determined to assist in identifying clubbing.[129] Hypertrophic pulmonary osteoarthropathy may be present in up to 5% of patients with non-small cell lung cancer (especially with squamous and adenocarcinomas) and 1% patients with small cell carcinoma.[130] HPOA is a systemic disorder, which involves both; a painful symmetrical arthropathy, usually of the ankles, wrists and knees, and periosteal new bone formation in the distal long bones of the limbs.[131]

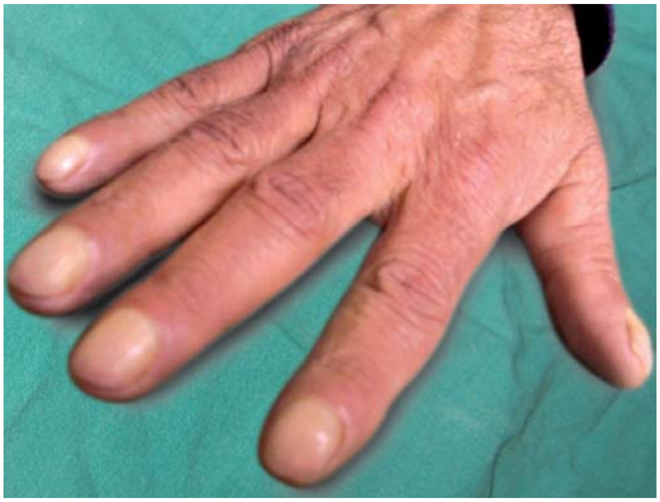

Fig. 117.10: Digital clubbing in a 56-year-old patient of squamous cell carcinoma of lung

The exact mechanism responsible for the development of clubbing and HPOA is not known. The past explanations included neurogenic, hormonal and vascular mechanisms.[132-134] Overexpression of Vascular Endothelial Growth Factor (VEGF) has been implicated in the pathogenesis. Bone scans show active deposition of new bone along the inner aspect of periostium. Clinically, HPOA responds well to surgical resection of the primary lung tumor. In unresectable tumors, corticosteroids and nonsteroidal anti-inflammatory drugs are used for symptomatic relief. For symptom relief, vagotomy can also be done, if thoracotomy is undertaken with an attempt to cure.[135]

MISCELLANEOUS SYNDROMES

There are various other unusual paraneoplastic syndromes known to be associated with bronchogenic carcinoma: renal (glomerulonephritis, nephrotic syndrome), vasculitic (systemic lupus erythematosus), systemic (fever, anorexia, cachexia) and metabolic (hypouricemia, lactic acidosis).[1,136] Several other endocrinal, neurological and hematological syndromes, in addition to those listed earlier can rarely occur.

Cutaneous manifestations of lung cancer are rare, include dermatomyositis-polymyositis, scleroderma, acanthosis nigricans, papillary dermatosis, erythema gyratum repens, erythema multiforme, exfoliative dermatitis, Sweet syndrome, pruritus and urticaria.[137] Adenocarcinoma and large cell bronchogenic carcinoma are known to be associated with gynecomastia due to tumor cell production of human chorionic gonadotropin, which results in overproduction of testicular estrogen.[138]

Diagnosis and Staging of Lung Cancer

Ajmal Khan, Navneet Singh

INTRODUCTION

The concept of staging in malignant disease originated from the historical observation that survival rates were better for patients with a localized tumor compared to those with advanced disease (widespread progression beyond the area of the primary tumor). The lung cancer staging system is aimed at providing a common basis for categorization of the extent of disease, plan of treatment, estimation of prognosis and ultimately for a comparison of the results of different treatment modalities on overall survival. Thus, accurate staging lays a foundation for grouping patients with similar prognosis and treatment plan and most importantly, identifies patients most likely to benefit from surgery. The optimal strategy for staging should be simple, accurate, noninvasive and cost-effective.

The goal of the initial diagnostic work-up is to both establish a diagnosis and provide sufficient additional information such that a definitive treatment plan can be developed in the most cost-effective manner. The staging should proceed in a sequential fashion with the aim of identifying patients who can be treated with curative intent as quickly and efficiently as possible, while minimizing expensive and invasive testing.[1,2] Similarly, the initial evaluation also needs to identify patients with advanced disease who have incurable disease and therefore minimize the risk of exposing them to the morbidity of surgery or combined-modality approaches.

Delay in the initial diagnostic workup can affect the stage, therefore reducing this delay could increase the detection of potentially resectable tumors and ultimately patient survival.[3]

DIAGNOSIS OF LUNG CANCER

Clinical Assessment (Also See Chapter 117)

The clinical evaluation remains the most important starting point in the work-up of a patient with suspected lung cancer. The initial evaluation, consisting of a thorough history and physical evaluation, is often used to establish a presumptive diagnosis and stage. However, it should also be followed by tissue diagnosis and the information obtained on initial clinical evaluation is utilized to guide further testing.

Majority of the patients with lung cancer present with symptoms like cough, hemoptysis, dyspnea, chest pain, hoarseness and wheezing, that are related to the primary tumor or intrathoracic spread of disease. Cough is probably the most common symptom of lung cancer at presentation, but one specific symptom that has been described to prompt more rapid evaluation is the hemoptysis.[4] Additionally, symptoms related to distant metastasis, paraneoplastic syndromes (Table 118.1) and/or nonspecific systemic symptoms such as fatigue, weight loss and generalized weakness may be present. Less than 10% of lung cancer patients are asymptomatic at presentation.[5,6]

Paraneoplastic syndromes are not directly related to the size or physical effects of primary or metastatic tumors. These occur in up to 10% of patients with lung cancer due to the production of biologically active substances such as polypeptide hormones, antibodies or cytokines. Occasionally one or more of these may precede the diagnosis of malignant disease, and at other times may occur later during the course of illness or may even herald the first sign of recurrence.

TABLE 118.1: Partial list of paraneoplastic syndromes associated with lung cancer[12]

Endocrine disorder
- Syndrome of Inappropriate secretion of Anti-diuretic Hormone (SIADH)
- Non-metastatic hypercalcemia
- Cushing syndrome
- Gynecomastia
- Hypercalcitonemia
- Hypoglycemia
- Hyperthyroidism
- Carcinoid syndrome

Neurologic syndromes
- Subacute sensory neuropathy
- Mononeuritis multiplex
- Intestinal pseudo-obstruction
- Lambert-Eaton myasthenic syndrome (LEMS)
- Encephalomyelitis
- Necrotizing myelopathy
- Cancer associated retinopathy

Skeletal disorders
- Hypertrophic osteoarthropathy
- Clubbing

Systemic syndromes
- Anorexia and cachexia
- Fever

Cutaneous
- Acquired hypertrichosis languinosa
- Erythema gyratum repens
- Erythema multiforme
- Tylosis
- Erythroderma
- Exfoliative dermatitis
- Acanthosis nigricans
- Pruritus and urticaria

Lung cancer is responsible for 46 to 75% of all cases of Superior Vena Cava Obstruction (SVCO) with Small Cell Lung Cancer (SCLC) being the most common histological subtype associated with SVCO.[7-9] SVCO is generally caused by the direct invasion of the tumor into the mediastinum or by lymphatic spread leading to enlarged right paratracheal lymph nodes. Mediastinal involvement and invasion to other vascular structures can also occur by direct extension. In lung cancer, pericardium is the commonest site of cardiac involvement leading to effusion or supraventricular arrhythmias.[10]

In lung cancer, distant metastasis occurs commonly to the brain, liver, bones and adrenal glands, but can also involve other body organs like spinal cord, lymph nodes and skin. Almost 30% of patients with lung cancer develop brain metastases and almost 10% of patients have intracranial metastasis at presentation.[11,12] Lung cancer is the most common primary site among all cancers metastasizing to the brain. Spinal cord metastases are less common and tend to occur in patients with cerebral metastases.

Radiological Assessment

Initial chest radiograph plays a pivotal role in the recognition of lung cancer that may present as a straightforward spiculated mass but its presence may also be inferred from other appearances such as an unresolving pneumonia or lobar collapse. However, the nonresolving radiographic appearance may be quite variable. In general, lung cancers present slightly more often on the right than the left side, and in the upper than in the lower lobes.[13-15] About 40% of the chest radiographic appearances of lung cancer are related to the central tumors causing airway obstruction with secondary atelectasis and consolidation.[16,17]

Once a pulmonary lesion is encountered, an important next step is comparison with old radiographs. Benign lesions typically have a prolonged doubling time of greater than 16 months. Doubling times of malignant nodules have been reported to vary from 40 to 360 days.[18] Conventionally, growth stability over a two-year interval is considered a reliable indicator for the presence of benign disease. Characteristics of the nodule on chest radiography may also be valuable. The presence of a spiculated margin, often termed as corona radiata, indicates a high likelihood of a malignant lesion, although a benign process such as a round pneumonia or scar may also manifest this sign.

Approximately two-thirds of squamous cell carcinoma occur centrally with involvement of a mainstem, lobar or segmental bronchus and associated with bronchial obstruction and obstructive pneumonia. Cavitation is seen more frequently in squamous cell carcinoma than in the other histological types.[19,20] Adenocarcinoma representing approximately 30% of all lung cancers is typically peripherally located with cavitation occurring in about 4% and mediastinal or hilar involvement in half of the cases.[21-23] Small cell lung cancer often presents with bulky hila and mediastinal lymph node metastasis with noncontiguous parenchymal mass and is rarely associated with cavitation.[22,24,25]

Establishing a Diagnosis

The decision to pursue a tissue diagnosis of the lung cancer depends on the initial presentation and clinical impression of the lesion, including the likelihood that it represents a primary lung cancer. For the lesions with lower likelihood of malignancy, a tissue diagnosis can be pursued best with sputum cytology or bronchoscopy if the lesion is located centrally, and a Transthoracic Needle Aspiration (TTNA) if the lesion is peripheral.[26] In the Duke University Center for Clinical Health Policy Research comprehensive review of the published literature, the average sensitivity and specificity of sputum cytology were 66% and 99%, respectively. In the same study, the overall sensitivity of flexible bronchoscopy for central tumors was 88%, compared with 69% for peripheral tumors. Among the bronchoscopic techniques, endobronchial biopsies were associated with the highest sensitivity (74%), followed by brushings (59%) and washings (48%). Similarly, for peripheral lesions larger than 2 cm, TTNA had a sensitivity of 62% as compared to 33% for the lesions that were smaller than 2 cm.[26] In a meta-analysis, the pooled sensitivity for differentiating between malignant versus all other categories by TTNA was 86.1% (range 83.8–88.45%) with a specificity of 98.8% (98.4 to 99.2%). However, the procedure was associated with very high incidence of pneumothorax [24.5% (range 3.1 to 41.7%)].[27]

A positive result from sputum cytology, bronchoscopy, or TTNA should be considered reliable because false-positive results typically have been reported to be less than 2%.[26,27] Although these modalities are useful in confirming the diagnosis, the false-negative rate for all three has not been well defined, or remains too high to rule out the diagnosis effectively. Therefore, if the clinical suspicion for a lung cancer diagnosis remains high, additional evaluation is usually required after a negative test result. In such cases for early diagnosis, special attention can be given to modern techniques like, Autofluorescence Bronchoscopy (AFB) and electromagnetic navigation.

In patients with simultaneous pleural effusion, diagnostic thoracentesis should be considered. The sensitivity of pleural fluid cytology is only 60%, which increases to 80% with three separate fluid specimens and therefore a minimum of three samples should be evaluated by an experienced cytologist.[28-31]

Once the tissue diagnosis has been achieved the final component of the diagnostic assessment is a functional evaluation of the patient including overall evaluation using performance status scales and evaluation for specific pulmonary status.

STAGING OF NON-SMALL CELL LUNG CANCER

If the diagnosis of Non-Small Cell Lung Cancer (NSCLC) is suspected based on the clinical presentation or has been confirmed by a tissue diagnosis, the new TNM system (Tables 118.2A and B) serves as the basis for the staging evaluation.[32-35] In this system, the major determinant chosen for development of subgroups of T, N, and M descriptors as well as the stage groupings was the overall survival, based on the best stage (pathologic, if available; otherwise clinical).[36,37] Overall, 40% of patients with NSCLC present with distant metastatic disease at presentation, 30% present with locally-advanced disease (stage IIIA/IIIB), while only the remaining 24% to 30% present in either stage I or stage II.[38] Two main methods of lung cancer staging are the clinical staging and the pathologic staging. Information provided by noninvasive or minimally invasive techniques, such as physical examination, radiologic examination, endoscopic ultrasound, bronchoscopy, mediastinoscopy and thoracoscopy prior to any treatment, are utilized for clinical staging. In pathologic staging, information obtained from clinical staging is combined with findings from both the invasive surgical procedure and the pathologic evaluation of the excised tissue.[39] Clinical staging helps to determine the next appropriate step in therapy, such as the decision to proceed with pathologic staging.

Mediastinal Staging

After a tissue diagnosis of lung cancer is established and surgical resection is the option, consideration must be given toward the determination of the extent of disease, or stage because this will impact directly the management and the prognosis. Mediastinal involvement is the threshold, at present, at which curative therapy may be implemented (IIIA is potentially curable while IIIB is not).[40] Thus, the status of regional lymph nodes is a major factor for staging, assigning treatment, and evaluating treatment efficacy in patients with lung cancer (Tables 118.3A and B).[41,42] Approximately 30 to 40% of patients with lung cancer already have mediastinal metastases at the time of initial diagnosis that necessitates histological or cytological evaluation of metastases to the mediastinal nodes.[43] Mediastinal lymph node staging can be divided into non-invasive (imaging) and invasive (sampling) procedures.

TABLE 118.2A: TNM System of staging NSCLC[35]

Descriptor	*Definition*	*Subgroups*
Primary tumor (T)		
T_0	No primary tumor	
T1	Tumor ≤3 cm, in the greatest dimension surrounded by lung or visceral pleura, not more proximal than the lobar bronchus	
T1a	Tumor ≤2 cm in the greatest dimension	T1a
T1b	Tumor >2 but ≤3 cm in the greatest dimension	T1b
T2	Tumor ≥3 but >7 cm in the greatest dimension or tumor with any of the following: Invades visceral pleura, involves main bronchus ≥2 cm distal to the carina, atelectasis/obstructive pneumonia extending to hilum but not involving the entire lung; T2 tumors with these features are classified as T2a if ≤5 cm	
T2a	Tumor >3 but ≤5 cm in the greatest dimension	T2a
T2b	Tumor >5 but ≤7 cm in the greatest dimension	T2b
T3	Tumor >7 cm	$T3_{>7}$
	or directly invading chest wall, diaphragm, phrenic nerve, mediastinal pleura,	$T3_{inv}$
	or parietal pericardium	
	or tumor in the main bronchus <2 cm distal to the carina	$T3_{Centr}$
	or atelectasis/obstructive pneumonitis of entire lung	$T3_{Centr}$
	or separate tumor nodules in the same lobe	$T3_{Satell}$
T4	Tumor of any size with invasion of heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body,	$T4_{Inv}$
	or carina	$T4_{Ipsi\ Nod}$
	or separate tumor nodules in a different ipsilateral lobe	
Regional lymph nodes (N)		
N0	No regional node metastasis	
N1	Metastasis in ipsilateral peribronchial and/or perihilar lymph nodes and intrapulmonary nodes, including involvement by direct extension	
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph nodes	
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene or supraclavicular lymph nodes	
Distant metastasis (M)		
M0	No distant metastasis	
M1a	Separate tumor nodules in a contralateral lobe	$M1a_{Contr\ Nod}$
	or tumor with pleural nodules or malignant pleural dissemination	$M1a_{Pl\ Dissem}$
M1b	Distant metastasis	M_{1b}
Special situations		
TX, NX, MX	T, N, or M status not able to be assessed	
Tis	Focus of *in situ* cancer	T_{is}
T1	Superficial spreading tumor of any size but confined to the wall of the trachea or mainstem bronchus	$T1_{SS}$

TABLE 118.2B: Stage groups according to TNM descriptor and subgroups[35]

T/M	*Subgroup*	*N0*	*N1*	*N2*	*N3*
T1	T1a	IA	IIA	IIIA	IIIB
	T1b	IA	IIA	IIIA	IIIB
T2	T2a	IB	IIA	IIIA	IIIB
	T2b	IIA	IIB	IIIA	IIIB
T3	$T3_{>7}$	IIB	IIIA	IIIA	IIIB
	$T3_{Inv}$	IIB	IIIA	IIIA	IIIB
	$T3_{Satell}$	IIB	IIIA	IIIA	IIIB
T4	$T4_{Inv}$	IIIA	IIIA	IIIB	IIIB

	$M1a_{Pl\ Disem}$	IV	IV	IV	IV
	M1b	IV	IV	IV	IV

Noninvasive Mediastinal Staging

The clinical staging of lung cancer is usually directed by noninvasive imaging tests that guide the likelihood of the presence or absence of metastatic involvement in the regional lymph nodes.

a. *Chest radiography:* At initial presentation of patients with lung cancer, majority of cancers are first detected or suspected on a plain chest radiograph. In selected patients, the chest radiograph may itself define spread of tumor to the mediastinum; however, in general this is an insensitive measure to detect mediastinal lymph node involvement and warrants further tissue confirmation as well as noninvasive and/or invasive assessment is required.

b. *Computed tomography (CT) of the chest:* A CT scan is relatively inexpensive, essentially performed as a preliminary step in order to define the nature of a pulmonary abnormality and to arrive at a clinical diagnosis of suspected lung cancer. CT scanning overall remains the best modality to study the anatomy of the thorax that guides the choice of nodes for selective node biopsy by invasive techniques. Computed tomography is the primary means of anatomic staging involving evaluation of the primary lesion, mediastinal lymphadenopathy and distant metastasis. It is also used adjunctively in the evaluation of local extension of central tumors into the mediastinum, into the chest wall, or invasion of superior sulcus tumors into the brachial plexus. The major limitations of anatomic imaging are the use of size criteria to define benign versus malignant lymph nodes, failure to distinguish tumor from atelectasis, and the nonspecific appearance of metastatic disease in general, which makes pathologic confirmation generally necessary.

The most widely used criterion to define the malignant involvement of mediastinal lymph nodes is a short-axis lymph node diameter of greater than or equal to 1 cm on a transverse CT scan. However, other criteria have also been used: A long-axis diameter of ≥1 cm, a short-axis diameter of greater than/equal to 1.5 cm, a short-axis diameter ≥ 1 cm plus evidence of central necrosis or disruption of the capsule and a short-axis diameter of ≥2 cm regardless of nodal morphology. The varied sensitivity and specificity for identifying malignant involvement in various studies is because of the use of these different criteria in the assessment of individual nodal stations.[44,45]

In a systematic review of 43 peer reviewed studies involving 5111 evaluable patients, the median prevalence of mediastinal metastasis was 28% (range, 18 to 56%) when presence of one or more lymph nodes measuring greater than 1 cm on the short-axis diameter was used as a cut-off to define a positive test. Additionally, in the same study, the pooled sensitivity and specificity of CT scanning for identifying mediastinal lymph node metastasis were 51 [95% Confidence Interval (CI), 47 to 54%] and 86% (95% CI, 84 to 88%), respectively. The corresponding positive and negative likelihood ratios were 3.4 and 0.6, respectively.[40] These data show that CT scanning

TABLE 118.3A: Mountain and Dresler regional lymph node classification for lung cancer staging[41]

Lymph Nodes	*Stations*	*Anatomic Landmarks*
Superior Mediastinal Nodes		N2 nodes: All N2 nodes lie within the mediastinal pleural envelope
• Highest mediastinal	1	Nodes lying above a horizontal line at the upper rim of the bracheocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline
• Upper paratracheal	2	Nodes lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of No. 1 nodes
• Prevascular and retrotracheal	3	Prevascular and retrotracheal nodes may be designated 3A and 3P; midline nodes are considered to be ipsilateral
• Lower paratracheal (including azygos nodes)	4	The lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope The lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the mediastinal pleural envelope
Aortic Nodes		
• Subaortic (A-P window)	5	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope
• Para-aortic (ascending aorta/phrenic)	6	Nodes lying anterior and lateral to the ascending aorta and the aortic arch or the innominate artery, beneath a line tangential to the upper margin of the aortic arch
Inferior Mediastinal Nodes		
• Subcarinal	7	Nodes lying caudal to the carina of the trachea, but not associated with lower lobe bronchi or arteries within the lung
• Para-esophageal (below carina)	8	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes
• Pulmonary ligament	9	Nodes lying within pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein
N1 Nodes		N1 nodes: All N1 nodes lie distal to the mediastinal pleural reflection and within the visceral pleura
• Hilar	10	Proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiogically, the hilar shadow may be created by enlargement of both hilar and interlobar nodes
• Interlobar	11	Nodes lying between the lobar bronchi
• Lobar	12	Nodes adjacent to the distal lobar bronchi
• Segmental	13	Nodes adjacent to the segmental bronchi
• Subsegmental	14	Nodes around the subsegmental bronchi

TABLE 118.3B: The IASLC lymph node map, including grouping of lymph node stations into“zones”[42]

Stations	Lymph Nodes
1	*Supraclavicular Zone*
	Low cervical, supraclavicular and sternal notch
Superior Mediastinal Nodes	
	Upper Zone
2R	Upper paratracheal (right)
2L	Upper paratracheal (left)
3A	Prevascular
3P	Retrotracheal
4R	Lower paratracheal (right)
4L	Lower paratracheal (left)
Aortic Nodes	
	Aortopulmonary Zone
5	Subaortic
6	Para-aortic (ascending aorta or phrenic)
Inferior Mediastinal Nodes	
	Subcarinal Zone
7	Subcarinal
	Lower Zone
8	Paresophageal (below carina)
9	Pulmonary ligament
N1 Nodes	
	Hilar/Interlobar Zone
10	Hilar
11	Interlobar
	Peripheral Zone
12	Lobar
13	Segmental
14	Subsegmental

has a limited ability to confirm or exclude mediastinal metastasis in patients with lung cancer. In two earlier meta-analyses, the median sensitivity and specificity of CT scanning for identifying malignant mediastinal nodes was reported to be 61% and 79%, and 64% and 74%, respectively.[46,47]

The major limitation of CT scanning is that approximately 60% of the nodes identified as malignant turn out to be benign and similarly, approximately 20% of all nodes identified as benign by CT criteria are actually malignant.[40,48] Thus CT scan tends to both understage and overstage status of mediastinal lymph nodes. Moreover, even if the CT criteria are met for malignant nodes, there is still a need to prove by biopsy or resection that the nodes are malignant.

c. *Positron emission tomography (PET) scanning: PET imaging with [18F]-fluoro-2-deoxy-D-glucose* (FDG)-PET is widely used to stage lung cancers and to assess therapeutic response and determine prognosis.[49-54] FDG, a glucose analog, is taken up via glucose transporter membrane proteins present in both normal and tumor cells. Intracellular FDG is then converted to FDG-6-phosphate by hexokinase, but unlike glucose does not enter further metabolism and remains trapped in cells.[55] The combination of increased uptake of ^{18}F-FDG and a decreased rate of dephosphorylation by glucose-6-phosphatase in malignant cells results in an accumulation of ^{18}F-FDG-6-phosphate in these cells.[56,57] The disintegration of positrons from ^{18}F emit high energy gamma rays at 180° which can then be detected, localized and imaged as areas of higher metabolic activity. The relative activity in a given structure as related to background physiologic activity is termed Standardized Uptake value (SUV). In order to calculate the SUV accurately, information of body weight and serum glucose are necessary. An SUV greater than 2.5 is generally considered suspicious for neoplasm. Importantly PET scanning is primarily a metabolic examination and has limited anatomic resolution. The integration of PET and CT fusion provides, precise localization of the lesions on the FDG PET scans within the anatomic reference frame provided by Computed Tomography (CT). This increases the specificity of the imaging modality.

Overall, in the setting of an undiagnosed pulmonary nodule of greater than 1 cm, ^{18}F-FDG PET has a sensitivity of 96.8% and specificity of 77.8% in the detection of malignancy.[58] Recently, in a systematic review of 44 studies, a pooled estimates of sensitivity and specificity for identifying mediastinal metastasis were 74% (95% CI, 69% to 79%) and 85% (95% CI, 82 to 88%), respectively. Corresponding positive and negative likelihood ratios for mediastinal staging with PET scanning were 4.9 and 0.3, respectively.[40] An additional benefit of PET scanning is its ability to provide information about the primary site in the chest along with the intrathoracic and extrathoracic metastases with a single study. The exception is in the evaluation for brain metastases; generally, PET is considered to be less accurate than CT or Magnetic Resonance Imaging (MRI) scanning, with a reported sensitivity of only 60%.[59] These findings demonstrate that PET scanning has both higher sensitivity and higher specificity than CT scanning for the evaluation of mediastinal lymph nodes as well as metastatic disease.

Infection, granulomatous disease, and sarcoidosis all may have increased metabolic activity and limit the specificity of PET. False negative results may occur with well differentiated adenocarcinomas, bronchioalveolar cell carcinoma, carcinoid tumors and lesions less than 1 cm.[60-62]

Integrated ^{18}F-FDG PET/CT imaging outperforms CT alone, ^{18}F-FDG PET alone, conventional visual correlation or superimposition of CT and ^{18}F-FDG PET acquired individually.[63-67] The diagnostic advantages include more precise demarcation of primary tumor, improved diagnosis of tumor invasion, demarcation of tumor within atelectasis or infection, more precise localization of mediastinal lymph nodes greater than 8 mm in size, as well as the precise localization of extrathoracic lesions.[68] Most notably, integrated systems allow more accurate staging impacting treatment decisions in up to 20% of patients.[63]

In interpreting PET-CT results, particular attention is needed for false-negative and false-positive results, identifying them and confirming by additional imaging studies, even biopsy is necessary for key management decisions.[69,70] A PET-CT finding that is discordant with the pretest probability of neoplastic involvement is a key clue to a false-negative or a false-positive PET-CT result. Hence, due to the limited diagnostic specificity for identifying mediastinal metastases, tissue proof of PET positive lesions are recommended to prove that the lesions are truly malignant before denying surgical resection.[71] In summary, PET scanning is the most accurate noninvasive imaging modality available to evaluate the mediastinum in patients with lung cancer.

Invasive Mediastinal Staging

Once the presumptive clinical stage with respect to the mediastinum is obtained by initial clinical evaluation and noninvasive testing, in many clinical situations confirmation of the status of these nodes by an invasive test is necessary. Imaging studies are not sufficiently reliable in many situations that makes these invasive tests an important part of appropriate staging. Several invasive tests with differing performance characteristics are available to stage the mediastinum. These include mediastinoscopy, the Chamberlain procedure (also known as an anterior mediastinotomy), Transthoracic Needle Aspiration (TTNA) of the mediastinum, Transbronchial Needle Aspiration (TBNA), Endobronchial Ultrasound (EBUS) with Needle Aspiration (NA), Esophageal Endoscopic Ultrasound (EUS) with NA, and Video-Assisted Thoracic Surgery (VATS).

The invasive procedures are required to more accurately confirm the presumptive mediastinal stage but in selected cases used simply to confirm the diagnosis of malignancy. When it is used for diagnosis only, the choice of the test is driven primarily by the patient-specific issues rather than the test-specific performance characteristics. In contrast when it is used to confirm the mediastinal stage, the choice of procedure is governed by how reliably the test will define the absence or presence of nodal involvement

a. *Mediastinoscopy:* Mediastinoscopy is performed under general or local anesthesia in an operating room as an outpatient procedure.[72-74] It involves an incision just above the suprasternal notch and biopsy of the mediastinal nodes after insertion of a mediastinoscope alongside the trachea. Nodes that are accessible via this approach are right and left high and low paratracheal nodes (stations 2R, 2L, 4R, and 4L), pretracheal nodes (stations 1 and 3), and anterior subcarinal nodes (station 7). While posterior subcarinal nodes (station 7), inferior mediastinal nodes (stations 8 and 9), Aortopulmonary Window (APW) nodes (station 5), and anterior mediastinal nodes (station 6) node groups cannot be biopsied with this technique. Ideally, five nodal stations (stations 2R, 4R, 7, 4L, and 2L) should routinely be examined, with at least one node sampled from each station unless none are present after actual dissection in the region of a particular node station.

   To detect mediastinal node involvement from cancer, average sensitivity and False Negative (FN) rate of mediastinoscopy is about 80% and 10% while the specificity and False Positive (FP) rate is 100% and 0%, respectively.[75-84] Among the false negative cases approximately 42 to 57% are due to nodes that were not accessible by the mediastinoscope.[85-87] Mediastinoscopy is associated with a complication rate of 2 to 3% and a surgical mortality rate of around 0.1%.[88-90]

b. *Chamberlain procedure (anterior mediastinotomy):* It involves an incision in the second or third intercostal space just to the left of the sternum to assess the node in the Aortopulmonary Window (APW) (station 5). Cancers in the Left Upper Lobe (LUL) have a predilection for involvement of the nodes in the APW. These mediastinal nodes represent the most important group of N2 nodes that are not accessible by standard cervical mediastinoscopy. When Chamberlain procedure is combined with standard cervical mediastinoscopy in patients with LUL tumors, the sensitivity and FN rate is approximately 87% and 10%, respectively.[84,91]

Extended cervical mediastinoscopy where a mediastinoscope is inserted through the suprasternal notch and is directed lateral to the aortic arch, offers an alternative method for the invasive assessment of APW nodes.[91,92] In two large series of extended mediastinoscopy in patients with LUL cancers, the sensitivity and FN rates ranged from 69 to 81% and 9 to 11% respectively. Thoracoscopy and EUS-NA provides an alternative method of sampling APW nodes

c. *Esophageal endoscopic ultrasound with needle aspiration (EUS-NA):* EUS-NA through the wall of the esophagus is particularly useful for inferior pulmonary ligament, esophageal, subcarinal, and APW nodes (stations 9, 8, 7, and 5). In various studies that assessed the use of EUS-NA in the mediastinal staging of 973 evaluable lung cancer patients, the overall sensitivity, specificity, FN and FP rate, was 84%, 99.5%, 19% (range, 0 to 61%) and 0.4%, respectively.[93-98] Similarly in a meta-analysis of 18 studies assessing the diagnostic accuracy of EUS-FNA, it was found that the pooled sensitivity and specificity of EUS-FNA were 83% and 97%, respectively. The sensitivity increased to 90% when the analysis was limited to patients who had abnormal mediastinal lymph nodes seen on CT scans, however, the specificity remained the same.[99] The performance characteristics of EUS-NA apply broadly to patients with cN0-cN1 tumors, because the technical issues are probably governed by the size of the nodes.

EUS-FNA is also capable of detecting metastatic disease to subdiaphragmatic sites such as the left adrenal gland, celiac lymph nodes and the liver. Similarly, evaluation for the presence of direct tumor invasion into the mediastinum can also be performed by EUS-FNA. Although EUS can be helpful in determining the T stage in less cost than the surgical procedure, its usefulness for treatment decisions is limited by the high FP rate.

The major limitation of EUS-FNA in lung cancer staging is the inability to assess nodes in the anterior mediastinum, resulting in an imperfect sensitivity. This is due to the fact that ultrasound cannot penetrate air-filled structures, so, nodes immediately anterior to the trachea (i.e. levels 2R, 4R, 3, and 6) are not well visualized.

d. *Transbronchial needle aspiration (TBNA):* Sampling technique of minimally invasive TBNA through the bronchoscope, originally described by Wang and Terry in 1983, has been shown to be an effective and safe technique in the diagnosis and staging of lung cancers.[100,101] TBNA is feasible for obtaining adequate specimens in approximately 80 to 90% of cases in lung cancer.[102-104] In a meta-analysis of 13 studies, Holty *et al.* using a random effects model, found that the pooled sensitivity and specificity of TBNA in mediastinal staging was 39% (95% CI 17 to 61) and 99% (95% CI 96 to 100), respectively. They concluded that when properly performed, TBNA is highly specific for identifying mediastinal metastasis in patients with NSCLC and the sensitivity depends critically on the prevalence of mediastinal metastasis.[101] Similarly in a recent systemic review of mediastinal staging with TBNA that included 17 studies, the sensitivity, specificity, FN and FP rates were 78% (14 to 100%), 100%, 28% (0 to 66%) and 0% respectively.[105]

The high FN rate of TBNA in the mediastinal staging and dependence of sensitivity on the prevalence of mediastinal metastasis makes this test less useful for staging of the mediastinum in patients with normal-sized nodes. Thus, negative TBNA results, however, cannot sufficiently exclude mediastinal nodal involvement, and additional staging procedures are required.

e. *Endobronchial ultrasound with needle aspiration (EBUS-NA):* Introduction of EBUS as a tool for NSCLC staging has led to a shift from systematic nodal sampling to targeted nodal sampling. With EBUS-TBNA the paratracheal (stations 2 and 4), subcarinal (station 7), hilar and intrapulmonary nodes (stations 10 and 11) can be reached. Compared with mediastinoscopy, EBUS-TBNA has the advantage of routinely accessing posterior mediastinal (level 7) and hilar lymph nodes (levels 10 and 11). The main blind spots for EBUS-TBNA are the lymph nodes in the aortopulmonary window, para-aortic station, paraoesophageal stations and the inferior pulmonary ligament. By localizing the lymph nodes with EBUS, the sensitivity of TBNA can be greatly increased up to the tune of 85%.[106]

In a comparative study, Yasufuku *et al.* found that as compared to CT and PET, EBUS-TBNA has a high sensitivity as well as specificity for mediastinal and hilar lymph node staging in patients with lung cancer.[107] The overall sensitivity reported for EBUS-TBNA was 90%, with values ranging from 79 to 95%. The average FN rate in general was 24% (range, 1 to 37%).[105] Similarly, a recent meta-analysis that included 10 studies found pooled sensitivity of specificity of 88% (95% CI 0.79 to 0.94) and 100% (95%

CI 0.92 to 1.00), respectively.[108] Because of the real-time imaging of nodes with EBUS and the immediate proximity of nodes to the airway, EBUS holds a great deal of promise for this staging method, even in small nodes.

f. *Transthoracic needle aspiration (TTNA):* The ability to perform TTNA for the diagnosis and staging of cancer in the mediastinum has generally been reported to be high (>90%), with a sensitivity of 90%, although approximately 10% ultimately land up with pneumothorax requiring tube placement.[109-113] Because of quite extensive mediastinal involvement in the patients included in the studies, the purpose of the procedure was probably to confirm the diagnosis and less likely to confirm the stage.

g. *Video-assisted thoracic surgery (VATS*): Video-assisted thoracic surgery done under general anesthesia can be used to access mediastinal nodes but its usefulness is limited to an assessment of only one side of the mediastinum. There is a wide variation in the sensitivity from 37 to 100% reported in various studies. An added advantage of VATS is the detection of unsuspected malignant pleural effusion and pleural studding in patients undergoing this procedure.

In conclusion, because of the absence of a striking difference in the sensitivity of various invasive mediastinal staging procedures, several issues must be considered before deciding the optimal investigation to be chosen in a given patient. These issues include:

- Availability and expertise of different procedures at a given centre/institution
- Location of the lymph nodes to be assessed for histopathological/cytological examination
- Patient's general medical condition including performance status and co-morbidities
- Morbidity and mortality of invasive procedures.

STAGING OF SMALL CELL LUNG CANCER

Traditionally, Small Cell Lung Cancer (SCLC) has been staged as either Limited Disease (LD) or Extensive Disease (ED).[114] This was chosen since the former denoted disease restricted to one hemithorax, with or without regional lymph node metastases and/or ipsilateral pleural effusion and thus could be encompassed within one radiation port. Lately it has been shown that use of the 7th edition of the TNM staging can prognosticate patients more accurately than the traditional system.[115] However, for management purposes, the role of surgical resection is limited in case of SCLC. Hence, invasive procedures of the mediastinum, if performed, are more for diagnostic purposes than for staging.

Approach to Management of Lung Tumors

Navneet Singh, Digambar Behera

INTRODUCTION

Lung tumors are an important group of pulmonary disorders that include both benign and malignant neoplasms. The most important disease entity in this group is lung cancer. Lung cancer is the most common cancer worldwide representing approximately 12% of all new cancers.[1] It is also the most common type of cancer in males and the most common cause of cancer related mortality in both sexes.[1,2] Lung cancer accounts for 17.6% of the total cancer related deaths which is far more than for any other type of cancer.[2] Furthermore, lung cancer mostly presents as an advanced disease.[3] Approximately 80% of cases are of Non-Small Cell Lung Cancer (NSCLC) type.[3] Overall, the prognosis for lung cancer remains dismal, the 5-year survival rates are at best around 15% despite available advances in treatment options.[4] This chapter focuses primarily on specific issues related to lung cancer in the Indian context.

DIAGNOSTIC WORK-UP

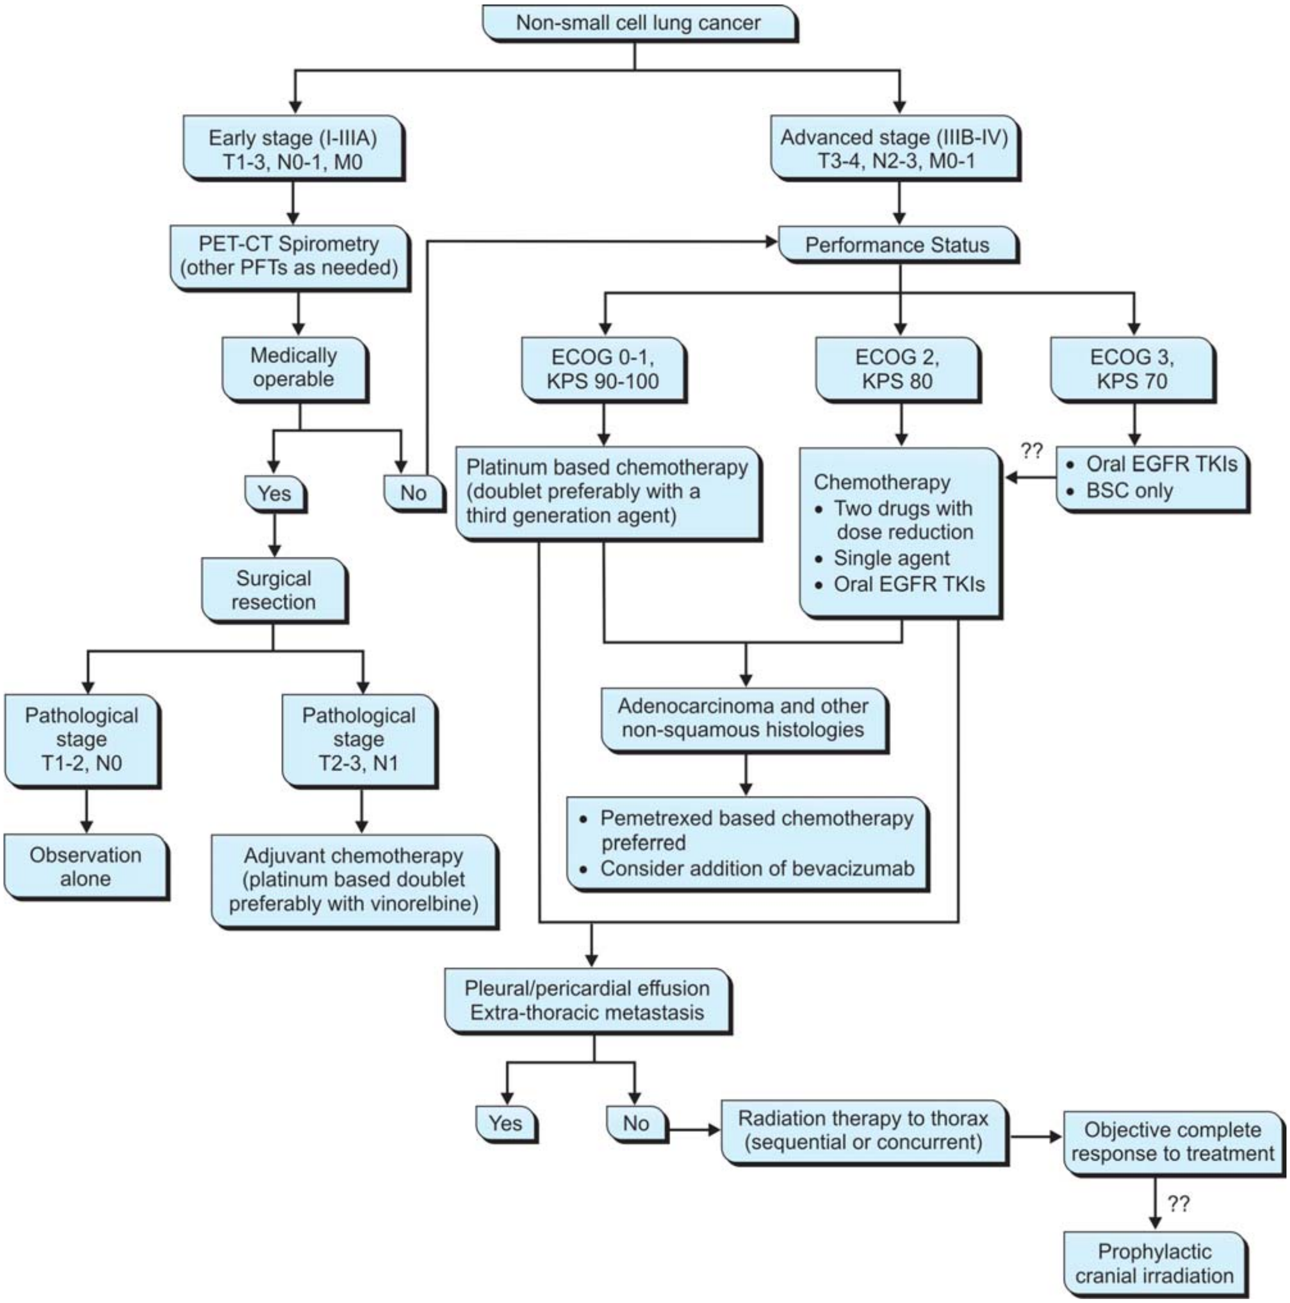
Details about the investigations needed to establish a correct diagnosis as well as for staging are given in other chapters. However, it is necessary to emphasize here that in any patient suspected to have a thoracic neoplasm, a contrast enhanced Computed Tomography (CT) scan of the thorax and upper abdomen (including liver and adrenals) is essential for better delineation of the anatomical extent of the tumor as well as for detailed structural assessment. In case of lung cancer, this is also necessary for ensuring that the patient is staged appropriately prior to initiation of treatment. Other imaging modalities are less useful but may be done for specific indications like Magnetic Resonance Imaging (MRI) scan for determining the extent of neural involvement in cases of superior sulcus tumors and Positron Emission Tomography (PET) scan for the functional (metabolic) assessment of a pulmonary/extrapulmonary lesion.[5]

The PET-CT scan which combines the metabolic assessment of PET scan with the structural/anatomical assessment of CT scan is more accurate for staging purposes than either of the two alone.[6] However, this facility is not routinely available in developing countries and is also more expensive than a normal CT scan. Hence, it is prudent that its use is restricted to patients in whom it can potentially lead to changes in management. For example, in a patient of NSCLC with obvious evidence of liver metastases on CT, a PET scan is unlikely to alter the management significantly. However, in a patient with potentially resectable (early stage) NSCLC on initial imaging, a PET-CT is necessary to rule out metastatic disease that may otherwise be inapparent radiologically and therefore to avoid an unnecessary thoracotomy.

It is also necessary to know that no imaging modality by itself can confirm the diagnosis of a lung tumor, which can be provided only by cytological and/or histopathological examination of a representative tissue/fluid specimen. The site and type of tissue/fluid obtained can vary depending upon the anatomical involvement and extent of the tumor. Commonly endobronchial biopsy and bronchial washings for endobronchial tumors, image guided fine needle aspiration and biopsy for peripherally located tumors, pleural fluid analysis and biopsy for tumors associated with pleural effusion and lymph node aspiration and biopsy for peripherally accessible lymph nodes are performed.

TREATMENT PLANNING

Conventionally, as is true for other cancers, the most important treatment modalities for lung cancer have been chemotherapy, surgical resection and radiation therapy. Management of lung cancer is traditionally discussed separately for NSCLC and small cell lung cancer (SCLC) since the surgery holds a very limited role in case of the latter due to its propensity for early dissemination/distant metastases. An algorithmic approach to the management of NSCLC and SCLC is depicted in Figures 119.1 and 119.2 respectively. In the recent past especially in the last couple of decades, targeted therapies have also emerged as a useful addition to the conventional armamentarium for the treatment of NSCLC. Platinum-based chemotherapy (conventionally in association with



Non-small cell lung cancer
Early stage (I-IIIA) T1-3, N0-1, M0
Advanced stage (IIIB-IV) T3-4, N2-3, M0-1

a third generation chemotherapeutic agent) remains an important component of the management protocol for almost all patients with NSCLC-early, locally advanced and metastatic.[7,8] The role of surgical resection and radiation therapy in NSCLC is predominantly for patients presenting with stages I-IIIA and IIIA-IIIB respectively (Table 119.1). For advanced/metastatic NSCLC, the current standard of care is chemotherapy alone. The greatest evidence is for the use of a platinum based doublet.[8] A detailed description of the different techniques and modalities available for surgical resection as well as technical aspects related to administration of radiation therapy remains beyond the scope of this chapter. The medical management is however discussed in further detail below.

There have been significant changes in the regimens used for treatment of this disease over the past few decades. Earlier, agents like vincristine, vinblastine, cyclophosphamide, ifosfamide, methotrexate, adriamycin and mitomycin-C were being used for treatment of NSCLC.[9-11] However, currently because of a more favorable toxicity profile, third generation agents (taxanes, gemcitabine, pemetrexed and vinorelbine) are the preferred drugs that are used in combination with a platinum agent. Chemotherapy along with Best Supportive Care (BSC) has been shown to be better than BSC alone in improving survival.[12-14] In addition to this quantitative effect, the benefit of chemotherapy over BSC alone has also been observed in terms of improvement in quality of life (QOL).[15-17]

In an attempt to practice personalized medicine, there are several considerations which the treating physician has to look into. The important ones are listed below:

1. **Choice of Platinum Agent:** The two commonly used platinum agents are cisplatin and carboplatin. An individual patient data meta-analysis involving 2968 patients from nine RCTs compared the efficacy of cisplatin versus carboplatin when used in first line chemotherapy for advanced NSCLC.[18] The objective response rate was observed to be higher with cisplatin

TABLE 119.1: Role of the traditional treatment modalities in different stages of non-small cell lung cancer

*Stage**	*Surgery*	*Chemotherapy*	*Radiotherapy*
IA	Yes	No	Only if medically inoperable
IB	Yes	? Yes (adjuvant)	Only if medically inoperable
IIA & IIB	Yes	Yes (adjuvant)	Only if medically inoperable
IIIA (non-bulky)	Yes	Yes (adjuvant or neoadjuvant)	Yes (post-operative)
IIIA (bulky)	Not routinely	Yes	Yes (sequential or concurrent)
IIIB (without pleural effusion)	No	Yes	Yes (sequential or concurrent)
IIIB (with pleural effusion)† and IV	No	Yes	Only for palliation

*Stage description based upon 6th edition of TNM staging system
† In 7th edition of TNM staging system, presence of a malignant pleural effusion is put in stage IV

than with carboplatin [30% vs 24% respectively, Odds Ratio (OR) = 1.37]. Carboplatin-based chemotherapy was associated with a statistically significant increase in mortality among patients with non-squamous histology [Hazards Ratio (HR) = 1.12] as well as those treated with third-generation chemotherapeutic agents (HR = 1.11).[18] Although cisplatin-based chemotherapy is associated with more severe nausea-vomiting and nephrotoxicity, carboplatin-based chemotherapy is associated with more severe thrombocytopenia.[19] Thus, cisplatin being slightly superior to carboplatin both for response rates as well as Overall Survival (OS), remains the standard drug for formulating a chemotherapy regimen while carboplatin is preferred for patients in whom there are relative contraindications to the use of cisplatin.

2. **Role of Histology:** There is a growing body of evidence to suggest that NSCLC is a heterogeneous disease although, as of now, all the different histological types continue to be clumped as one disease entity. It has been shown in both prospective and retrospective studies that squamous histology remains a favorable prognostic factor for patients undergoing lung resectional surgery.[20-23]Infact, in the JBR.10 trial, presence of squamous histology was the only factor other than administration of chemotherapy that was associated with both an improvement in OS as well as in recurrence-free survival among patients with completely resected early-stage NSCLC.[20] The converse has however been observed for patients with unresectable disease.[24,25] In addition to being a prognostic factor, histological type remains an important predictive factor also for different therapeutic modalities in NSCLC.[26] Differences in treatment responses based on histology have indeed been observed in recently published Randomized Clinical Trials (RCTs).[27,28] Results of recently published phase III RCTs involving the use of pemetrexed (an anti-folate drug that inhibits multiple enzymes involved in purine and pyrimidine synthesis) suggest that patients of NSCLC with different histological patterns may respond differently to commonly used chemotherapeutic agents.[29-31] In one study, pemetrexed was compared with gemcitabine in previously untreated patients with advanced NSCLC.[30] Both the chemotherapy regimens were platinum based doublets. Among patients with adenocarcinoma, OS was statistically superior for those who received pemetrexed compared to gemcitabine (12.6 vs 10.9 months; HR = 0.84) while the reverse was seen in patients with squamous cell histology (9.4 vs 10.8 months; HR = 1.23). Patients with large cell and non-squamous histology (as a group) had results similar to those seen with adenocarcinoma.

Even in the second line/maintenance therapy setting, pemetrexed has been demonstrated to result in superior median OS for patients with adenocarcinoma and non-squamous histology, in two phase III RCTs.[29,31] In the RCT comparing pemetrexed to docetaxel as second line therapy for advanced NSCLC, among subgroup with squamous histology, patients treated with pemetrexed had statistically worse OS than those receiving docetaxel.[29,32] In the other trial wherein pemetrexed was used as maintenance therapy after initial treatment with a platinum based doublet, the drug fared no better than placebo, in terms of its effect on OS among the subgroup of patients with squamous histology.[31] In addition, pemetrexed has a superior tolerance and lesser toxicity profile than the other agents with which it has been compared in the above mentioned RCTs.

Histology plays a very important role in decision making. Currently adenocarcinoma and non-squamous NSCLC histologies are preferably treated with pemetrexed. However, it needs to be mentioned that pemetrexed is the most expensive of all the third generation agents which are available. Even if a generic brand is used, the cost can sometimes reach up to 50,000 Indian Rupees (INR). Even if a patient is otherwise a candidate for pemetrexed treatment (non-squamous NSCLC histology), he/she may not always able to afford the drug due to a significant difference in the cost of the regimen compared to the other available agents. The issue of cost versus the benefits must be clearly discussed with the patient/family. Not infrequently, the benefit may in fact be too small compared to a significant different in the cost.

3. Choice of Third Generation Agent to be Used with Platinum Compound: Both the commonly used platinum compounds are quite cheap compared to any of the third generation agents which form the two drug regimen. This is one of the reasons why non-platinum regimens are infrequently used even in the case of intolerance or contraindications to use of plantinum compounds. Most of the third generation agents like paclitaxel, docetaxel, gemcitabine and vinorelbine are similar in efficacy (Table 119.2).[33] At our center, paclitaxel-cisplatin is the cheapest regimen among all the above. This is in part due to use of a lower dose [175 mg/m^2 Body Surface Area (BSA) given on day 1 of a three weekly cycle] as compared to relatively higher doses (200 to 225 mg/m^2 BSA) being used at other centers in the developed countries.[34] Gemcitabine and vinorelbine both share the same disadvantage, that two visits are required for a given cycle, since these drugs are generally given on two days (day one and day eight of a three weekly cycle). The taxanes (paclitaxel, docetaxel) on the other hand are given on day one only. For a center where majority of the patients come from distant areas, the frequency of visits to be made for a given cycle often holds a great importance.

4. Number of Cycles: As regards to the optimal duration of chemotherapy, it is recommended that the initial chemotherapy regimen should be administered for a maximum of four to six cycles.[8] What we follow, as is done by several centers in North America and Europe, is to continue the initial regimen for four cycles (in the absence of obvious disease progression). An assessment of the response to therapy is done most commonly by repeat contrast enhanced CT scan of the thorax and upper abdomen (to include liver and adrenal glands). Response assessment can be done by using either the RECIST or WHO criteria.[35,36] An addition of two cycles can be considered for patients who show a response (partial/complete). There is little benefit in giving the same regimen in the presence of stable disease after four cycles, while second line therapy is warranted if there is evidence of disease progression at any point during the initial treatment. Even for responding patients, no more than six cycles should be given.[37]

TABLE 119.2: Comparison of efficacy of four chemotherapeutic regimens (modified and adapted from reference 33)

Regimen	*Paclitaxel + Cisplatin*	*Gemcitabine + Cisplatin*	*Docetaxel + Cisplatin*	*Paclitaxel + Carboplatin*
Schedule	135 mg/m^2 (over 24 hours) on day 1 + 75 mg/m^2 on day 2 every 3 weeks	1000 mg/m^2 on days 1,8,15 + 100 mg/m^2 on day 1 every 4 weeks	75 mg/m^2 each on day 1 every 3 weeks	225 mg/m^2 (over 3 hours) + AUC* 6 on day 1 every 3 weeks
Response rates†

† For each group, complete response was ≤1%

§ Data is presented as median (95% confidence intervals)

PR: Partial Response; SD: Stable Disease; PD: Progressive Disease; TTP: Time to progression

5. **Dose Intensity:** Dose Intensity (DI) is defined as the dose of a particular chemotherapeutic drug administered per unit time, expressed as milligrams per metre square of body surface area per week ($mg/m^2/week$).[38] Dose intensity is used to indicate both the actual DI used as well as the relative DI. The latter is the ratio of DI of an experimental versus a standard regimen or of the delivered versus planned DI of a given regimen. This is a very important consideration in countries like India where there are constraints related to the availability of health care resources and where a majority of the population is not covered by medical insurance.

The treating physician is faced with the challenge of optimizing treatment efficacy and at the same time, avoiding complications related to chemotherapy. Moreover, DI can be increased either by increasing the dosage per session of chemotherapy and keeping the inter-session interval constant, or by reducing the inter-session interval and keeping the dosage constant.[38] The former can be associated with a higher degree of intolerance/acute toxicity while the latter requires an increased frequency of visits by the patient during a given time period. It is also important to differentiate DI from high dose therapy.[39]

6. **EGFR Targeted Therapy in the First Line Setting:** Targeted therapies have been tried as an alternative to, in conjunction with or following failure of standard chemotherapy regimens. Of the targeted therapies, the most extensive research has been conducted on the oral Tyrosine Kinase Inhibitors (TKIs) of the Epidermal Growth Factor Receptor (EGFR). The latter is frequently, although variably, expressed in tumor cells of patients with NSCLC. Gefitinib and erlotinib are the two EGFR-TKIs that are currently marketed and are available for use in routine clinical practice. Four large RCTs (INTACT-1, INTACT-2, TALENT, TRIBUTE) have failed to show any additional clinical benefit of adding an EGFR-TKI to chemotherapy in the first-line therapy of advanced NSCLC.[40-43] These drugs can however, be considered as an alternative to conventional chemotherapy for patients with poor Performance Status (PS).[44-47] However, the best predictors for response to this class of drugs is the presence of specific mutations in the EGFR gene.[48] Such testing is not commonly available in developing countries and even if available, may not be affordable by a large section of the patient population.[49]

In contrast, the role of EGFR targeted monoclonal antibody (cetuximab) in the first line setting has been somewhat different. EGFR gene copy number as determined by Fluorescent In Situ Hybridization (FISH) has been shown to be helpful in predicting outcome among patients treated with cetuximab.[50] In a large phase III RCT, this drug when combined with chemotherapy was shown to significantly improve OS as compared to chemotherapy alone when used as front line therapy for EGFR-FISH positive advanced NSCLC patients.[51] However, for a drug with no generic substitutes being available till date, the cost of this additional therapy is prohibitory for most Indian patients with no access to medical insurance or reimbursement of medical expenses.

7. **Single Agent:** Patients with sub-optimal PS (generally ECOG PS of 2 or less and Karnofsky PS of 80 or less) can be considered for single agent chemotherapy.[52] Non-platinum agents like docetaxel, gemcitabine and vinorelbine have been shown to be a good treatment option for such patients as well as for patients in whom there is intolerance to or contraindications for combination therapy with platinum agents.[45]

8. **Addition of Bevacizumab to Chemotherapy:** For selected subgroup of patients (non-squamous histology, peripheral tumors, absence of hemoptysis or CNS metastasis), addition of bevacizumab (a vascular endothelial growth factor [VEGF] monoclonal antibody) is associated with improved response rates and even overall survival.[53] The commonly used doses are 7.5 mg/kg body weight and 15 mg/kg body weight.[53,54] The greatest hindrance to its use is not medical but the cost of the therapy. For an average adult weighing 60 kg, the cost of this drug (for which no generic substitutes are available till date) is in excess of 100,000 Indian Rupees (INR) even at the lowest dose used clinically, namely 7.5 mg/kg. This exceeds the cost of chemotherapy by a factor of two or more. Furthermore, its use is recommended till disease progression which differs from that for chemotherapy for which a maximum of four to six cycles are recommended.

The expected life span and severity of symptoms are other additional factors that influence the choice and sequence of treatment for a given patient (Table 119.3). The optimum treatment protocol is also determined by tumor histology (Table 119.4). In the second line setting also, considerations for treatment are similar to those for the first line therapy and generally a drug other than the one used in the first line setting is chosen.[55]

The basic principles of chemotherapy for treatment of SCLC are the same as for NSCLC. As in the case of NSCLC, regimens containing drugs like vincristine,

TABLE 119.3: Factors determining choice of treatment modality for a given patient with lung cancer

cyclophosphamide, ifosfamide and lomustine were used frequently in the past for treatment of SCLC.[56,57] Currently, a platinum based doublet remains the preferred regimen: The agents used in the platinum doublet are either etoposide or irinotecan. The important differentiating feature from NSCLC is that there are limited therapeutic options both in first and second line settings since none of the targeted agents has shown significant clinical benefit till date as to warrant approval for use in routine practice. Most of the standard schedules currently practiced in India, employ a 3-week cycle frequency for both NSCLC and SCLC (Table 119.5).

PALLIATION

A high percentage of lung cancer patients have locally advanced/metastatic disease (stages IIIB/IV) at presentation or relapse after initial treatment. This group of patients often has significant symptoms related to disease. In such cases, the primary aim of management is to achieve symptom relief and improve the QOL. As is true for all patients with advanced cancers, attempting treatment with a curative intent is generally not possible. However, these patients remain candidates for palliative treatment which is not only necessary but also justifiable.[58]

Palliation is an important aspect of management of lung tumors especially advanced lung cancer (Table 119.6).

1. Treatment of locally advanced (especially endobronchial) disease for troublesome symptoms of cough, dyspnea and hemoptysis, is an important part of palliative care of lung cancer. Interventional bronchoscopy, wherever available, is helpful in alleviation of these symptoms since several procedures to relieve endobronchial obstruction can be performed.[59,60] Wherever available, intra lesion brachytherapy is another useful option for this purpose.[61]
2. Treatment of advanced mediastinal disease depends upon the structure that is being involved by the disease process.
    a. Relief of Superior Vena Cava (SVC) compression is commonly achieved by administration of radiotherapy in case of NSCLC and chemotherapy in SCLC.[62] Stenting of the SVC, in institutes which

have the facilities for a the same, is a good alternative/adjunct to the above measures.[63]

b. Tracheo-esophageal fistula often requires assessment from both a gastroenterologist and a pulmonologist in order to decide about the best possible intervention that can help in alleviating the symptoms attributable to the fistula. Stenting of the esophagus, trachea or both can prove to be useful in achieving relief.[64-67]

3. Treatment of metastatic disease

a. Malignant pleural and pericardial effusion. Malignant pleural effusion is discussed in another chapter. Malignant pericardial effusion is not infrequently seen in advanced lung cancer, especially among patients who have a malignant pleural effusion. Patients with malignant pericardial effusion can present with insidious onset progressive dyspnea or sometimes with features of cardiac tamponade. Prompt drainage of the effusion is necessary to achieve symptom relief and remove the tamponade. Creation of a pericardial window and intrapericardial sclerosis (by injection of a sclerosing agent into the pericardial space) are more definitive measures. The latter has been shown to be as effective and more cost-effective than open surgical drainage in several studies.[68-70] Unlike benign causes of pericardial effusion where intrapericardial sclerosis is a relative contraindication, the expected life span for a patient with malignant pericardial effusion is generally less than the time taken for a potential complication like pericardial constriction to develop from the procedure.

b. Bone: Bone metastases is a common but under-diagnosed entity among patients with lung cancer.[71] Bisphosphonates are recommended for use in patients with proven osteoskeletal metastasis.[72] Zoledronate is the most widely used drug for this purpose. It has been shown to reduce skeletal complications especially the incidence of Skeletal Related Events (SREs) like pathological fractures in patients with established bony metastasis.[73] The aim of using this drug is to both prevent and delay the occurrence of further bone metastases and SREs as well as to achieve pain relief. It is recommended that this treatment should continue for as long as it is practically feasible in the absence of any significant adverse effects.[72] In addition, local radiotherapy to the affected site helps in more rapid relief of symptoms.

c. Brain and Spinal Cord: Here again, radiation therapy has an important role in providing

TABLE 119.6: Important components of palliation during management of lung tumors

      - Ischemic heart disease
      - Depression

symptomatic relief. Corticosteroids are used for the same purpose although there is a ceiling to both the dose used as well as the duration for which they provide clinical benefit.[74]

4. Treatment of non-metastatic disease
   a. Anemia: This is more frequently encountered than the other cytopenias during chemotherapy of lung cancer patients in our setting.[34] Oral hematinics and blood transfusion for a greater severity of anemia, remain the most cost-effective method of correcting anemia. Erythropoietin stimulating agents are not only expensive but their usage is also associated with increased incidence of thromboembolic events. Hence they should be used only during the period of chemotherapy and not before or afterwards.[75,76]

   b. Cachexia: Cancer associated cachexia is not uncommonly seen in patients with advanced lung cancer. This symptom complex includes weight loss, anorexia, fatigue and generalized wasting. It is difficult to reverse cachexia in the absence of any definitive therapy for the disease. Patients who receive and respond to chemotherapy or targeted therapy show improvement. Progestins (especially megestrol acetate) have been tried for this paraneoplastic syndrome with variable success.[77]

   c. Deep Venous Thrombosis (DVT) and Pulmonary Thromboembolism (PTE): Both are known to occur more frequently among cancer patients than in the general population since cancer is one of the hyper-coagulable states. However, routine DVT prophylaxis in ambulatory cancer patients is not recommended.[78] Treatment is also similar to that seen in other situations.

5. Treatment of complications of chemotherapy:
   a. Infection: Both pulmonary and extrapulmonary infections may occur among patients with lung tumors. Postobstructive pneumonia is a frequent occurrence among patients with central tumors arising from and occluding a major or lobar bronchus. Typical features of postobstructive pneumonia include recurrent episodes involving the same anatomical area, paucity of expectoration

(unless the obstruction is incomplete) and lack of complete response to antimicrobial therapy. Postobstructive pneumonia is more likely to occur in an untreated patient.

Pulmonary infections are more common after definitive treatment especially with systemic cytotoxic chemotherapy and/or radiation therapy. Pulmonary infections can often present with and be treated in a similar way as they occur in immunocompetent individuals. The treating physician has to be vigilant about the presence of unusual etiological organisms and of unusual clinical features and in such cases, a more aggressive management strategy may be warranted. Extrapulmonary infections are more likely to occur among patients who have received systemic therapy as mentioned above. Presence of neutropenia may be associated with an increase in the incidence, severity and poorer outcomes.

   b. Peripheral Neuropathy: Generally, a complication of chemotherapy with taxanes and platinum agents, it can also occur as a paraneoplastic manifestation. Anticonvulsants and tricyclic antidepressants are used for the treatment of neuropathic pain.[74]

6. Treatment of co-morbid illnesses
   a. COPD: Smoking is an important risk factor for the development of both chronic Obstructive Pulmonary Disease (COPD) and lung cancer. Undiagnosed or inadequately treated airflow obstruction due to COPD can have an adverse effect on the QOL of patients with lung cancer.[58] Spirometric evaluation is a simple and effective measure to detect coexistent COPD. Smoking cessation is the most important intervention to retard progression of COPD. Patients should be assessed for the 5 'A' strategy if they have not quit smoking at the time of initial evaluation.[79] Bronchodilators (inhaled and oral) are important pharmacological measures for providing symptomatic relief.
   b. Depression: It is not uncommon to see depressive symptoms subsequent to the diagnosis and treatment of lung cancer.[80] Some patients may actually fulfill the criteria for major depression. There are even suggestions that addition of a specific intervention for its treatment to the usual standard of care for lung cancer, may actually influence the efficacy of the latter.[81]

Solitary Pulmonary Nodule

Alladi Mohan, B Vijayalakshmi Devi, Abha Chandra

INTRODUCTION

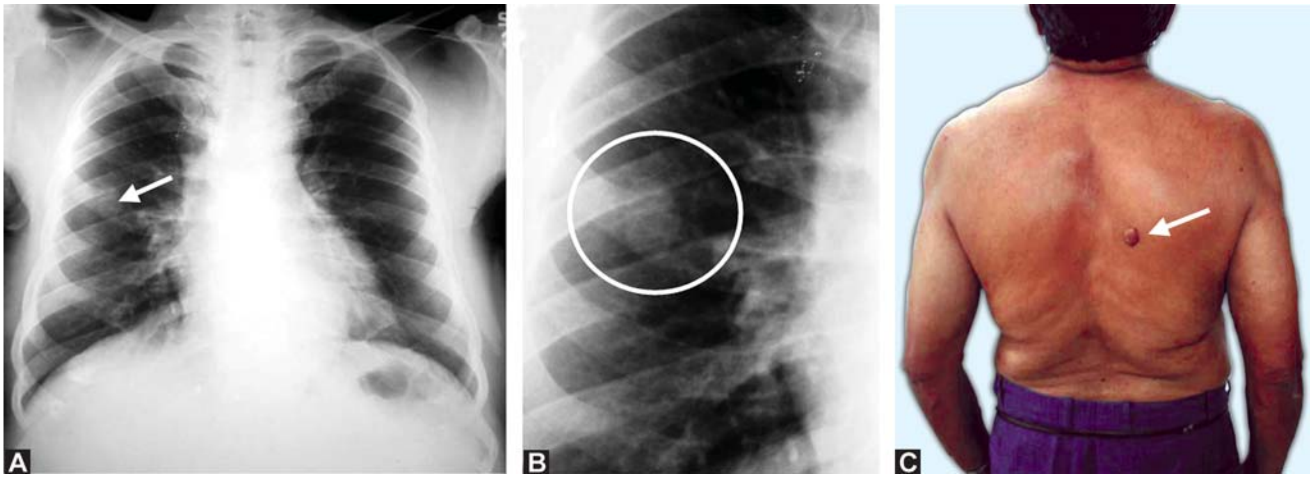
Solitary Pulmonary Nodules (SPNs) are small, focal, radiographic opacities that may be caused by a variety of benign and malignant disorders and constitute a unique diagnostic problem faced by pulmonologists, radiologists and thoracic surgeons.[1-4] In the earlier days of conventional radiography, these lesions used to be most commonly encountered as incidental findings on a chest radiograph. In the present era, widespread use of Computed Tomography (CT) has resulted in a significant increase in the detection of these lesions.[5,6] Many patients with early-stage lung cancer can present with an SPN. The overall 5-year survival rate in patients with lung cancer is poor ($\leq$15%); in comparison, long-term survival in stage IA lesions that can be resected may be as high as 80%.[1,7,8] Therefore, it is important to distinguish whether the lesion is benign or malignant so that early intervention is possible in patients with lung cancer and unnecessary surgery can be avoided in patients with benign SPNs.

Advances in CT technology, such as Multidetector-Row CT (MDCT) for the evaluation of lung and cardiovascular disease, Computer-Aided Diagnosis (CAD), 18F-Labeled 2-Deoxy-D-Glucose Positron Emission Tomography (FDG-PET), have markedly influenced the diagnostic work-up of a patient presenting with an SPN.[5,6] Comprehensive evaluation of an SPN requires careful consideration of a variety of patient-related variables, imaging findings appropriate use of invasive sampling and logistics related to a meticulous follow-up schedule.

TERMINOLOGY

The term "coin lesion" should not be used to describe SPNs because coin lesion implies a flat two-dimensional structure.[7-9] The SPN is defined as a single, spherical, well-circumscribed, radiographic opacity that measures less than or equal to 3 cm in diameter that is surrounded completely by aerated lung and is not associated with atelectasis, parenchymal infiltrates, hilar or mediastinal lymphadenopathy, or pleural effusion.[7-9] Focal pulmonary lesions that are greater than 3 cm in diameter are called "lung masses" and are commonly the manifestations of bronchogenic carcinoma. The lung nodules that measure less than 8 to 10 mm in diameter are called "subcentimeter" nodules, and are much less likely to be malignant. They are difficult to accurately characterize by imaging modalities, and are often difficult to approach by needle biopsy.[7-9] Thus, for practical purposes, the term SPN is used in the context of lung nodules that are at least 8 to 10 mm, but less than or equal to 3 cm in diameter.

The SPN has to be distinguished from multiple pulmonary nodules because the diagnostic significance and the algorithm for work-up of such lesions are different. Furthermore, up to 20% of SPNs observed on chest radiographs may in fact be nonpulmonary in origin when investigated by other methods and may represent nipple shadow, skin lesions (Figs 120A.1A to C), rib fracture, end-on-view of blood vessels, composite shadows or monitor leads.[10]



Figs 120A.1A to C: Chest radiograph (posteroanterior view) of a patient referred for further evaluation showing an SPN in the right mid-zone (arrow) (A); close-up view (open circle) of the SPN (B); Clinical examination revealed that the lesion was a cutaneous papilloma mimicking an SPN (C)

EPIDEMIOLOGY

World Scenario

In an early study[11] SPN was found in 1 of 500 (0.2%) chest radiographs that were obtained in community settings. More recently, about 7% of healthy volunteers (n=1000) in New York who participated in the Early Lung Cancer Action Project (ELCAP)[12] were found to have between one and three nodules on baseline screening chest radiograph; in a majority of them (76%), the largest nodule measured less than 1 cm. Overall, the estimated prevalence of SPN in published literature ranges from 8 to 51%.[13-15]

India

Though there have been occasional case reports on this topic, reliable epidemiological data on the true incidence of SPN are lacking from India. Pulmonary tuberculosis has occasionally been documented to present as an SPN in some studies from India.[16,17] At the Sri Venkateswara Institute of Medical Sciences (SVIMS), Tirupati, during the period 1996 to 2000, 23 patients with SPN underwent thoracotomy for the confirmation of diagnosis. On histopathological examination, etiological diagnosis in a majority of them was tuberculosis (n=15; 65%) and bronchogenic carcinoma (n=5; 22%).[18]

ETIOLOGY

Various etiological causes that manifest as an SPN are listed in Table 120A.1. The etiological spectrum varies depending on the age group, geographical location of the patient, prevalence of risk factors for lung cancer, among others. Common benign causes of SPN include active granulomatous infection (e.g. tuberculosis), hamartoma, lung abscess, round pneumonia, round atelectasis, bronchogenic cyst, hydatid cyst, healed pulmonary infarcts, focal hemorrhage, hemangiomas, and arteriovenous malformations, among others. Most common causes of malignant SPN are adenocarcinoma (47%), squamous cell carcinoma (22%), solitary metastasis (8%), undifferentiated Non-Small Cell Lung Carcinoma (NSCLC) (7%), Small Cell Lung Cancer (SCLC) and bronchioloalveolar cell carcinoma (4% each).[7]

CLINICAL EVALUATION

Majority of the patients presenting with an SPN are asymptomatic with the lesion being picked up incidentally in a chest radiograph or CT carried out for some other purpose. Clinical evaluation of a patient with SPN begins with obtaining a detailed history, and conducting a thorough physical examination (Table 120A.2). This is followed by appropriate imaging investigations and interventions for procuring tissue for cytopathological or histopathological diagnosis.

Age of the patient is an important clue and one of the independent factors predictive of malignancy in an SPN.[1,7,19] Malignancy is rarely a cause of SPN in patients under 30 years of age; older the patient, higher is the likelihood that the SPN is caused by a malignancy. A history of current or remote malignancy (especially lung cancer or head and neck cancer), significantly increases

TABLE 120A.1: Etiological causes of a solitary pulmonary nodule

Developmental
- Bronchogenic cyst
- Bronchial atresia with mucoid impaction
- Sequestration

Infections
- Tuberculosis
- Fungal infections (e.g. coccidioidomycosis, histoplasmosis, cryptococcosis and aspergillosis)
- Organizing pneumonia
- Lung abscess
- Septic embolus
- Round pneumonia
- Fungal infection (*Aspergillus*)

Neoplastic
- ***Benign***
  - Hamartoma
  - Chondroma
  - Teratoma
  - Leiomyoma
  - Endometriosis
- ***Malignant***
  - Carcinoma
  - Metastasis
  - Carcinoid tumor

Vascular
- Arteriovenous malformation
- Pulmonary infarction
- Hematoma
- Pulmonary artery aneurysm

Lymphatic
- Intrapulmonary lymph node
- Lymphoma

Inflammatory
- Rheumatoid nodule
- Wegener's granulomatosis
- Sarcoidosis

Airway
- Mucus impaction (e.g. bronchiectasis)

Others
- Rounded atelectasis
- Amyloidosis

TABLE 120A.2: Parameters to be considered in the evaluation of a patient presenting with an incidentally detected solitary pulmonary nodule

Clinical
- Age
- Smoking history
- Presence of other risk factors for lung cancer
- Current or remote history of malignancy

Radiological
- Size of the lesion
- Site where it is located in the lung
- Presence of calcification
- Growth rate
- Edge characteristics (smooth, spiculated, lobulated)
- Internal characteristics*
- Contrast enhancement

* include the attenuation, satellite nodules, presence of air bronchogram, halo sign, reverse halo sign, growth rate, wall thickness in cavitary nodules

Based on references 1,7,8

the probability of a malignant SPN.[19-21] However, the probability of the SPN being a metastatic lesion in the absence of a known prior malignancy is low.

History of tobacco smoking and other established exposures associated with an increased risk of lung cancer, such as, silica, air pollution, arsenic, cadmium, chromium and radiation (e.g. radon, X-rays and gamma rays) should be obtained. Other important clinical factors in the evaluation of the etiology of SPN include a history of hemoptysis, fever, constitutional symptoms (tuberculosis), and travel history (fungal, parasitic diseases); Human Immunodeficiency Virus (HIV) infection, among others. Meticulous physical examination is helpful in identifying mimics of an SPN, such as nipple shadow, skin lesions or monitor leads.

Some workers have developed models for predicting a malignant etiology in a patient with SPN. Herder and associates[22] using multiple logistic regression analysis described older age, current or past tobacco smoking history, and history of extrathoracic cancer more than 5 years before nodule detection as the independent predictors of malignancy. Gould and colleagues,[23] using multivariate analysis found current or former smoking status, increasing age, increasing nodule diameter, and decreasing interval since smoking cessation to be the predictors of a malignant SPN. There have also been other attempts at predicting malignancy using the likelihood ratio form of Bayes' theorem[24] and neural networks.[25,26]

IMAGING STUDIES

Chest Radiograph

The evaluation of an SPN usually begins with a review of the chest radiograph. Use of nipple markers or apical lordotic projections may help to distinguish normal anatomic structures from lesions causing an SPN. However, SPNs are often missed on the chest radiograph even by experienced chest radiologists, especially if they are located below the diaphragm or behind the clavicle, rib or heart. Availability of dual-energy subtraction digital chest radiograph systems is expected to improve the pick-up rate of SPNs in chest radiographs. Sometimes, characteristic radiological patterns of calcification, are suggestive of a presumptive diagnosis. Presence of diffuse, central, laminated and popcorn patterns of calcification are considered to be of benign etiology. But, stippled and eccentric patterns of calcification should prompt further work-up to rule out malignant etiology.[3,5]

When available, the current chest radiograph should be compared with a previous chest film. This will also facilitate the estimation of the growth rate (doubling time) of the SPN.

Computed Tomography

The CT is the primary imaging modality in the evaluation of a patient with an SPN. The CT by identifying whether the lesion is single or multiple (Fig. 120A.2) and by detecting other lesions, such as atelectasis, other parenchymal infiltrates, hilar or mediastinal lymphadenopathy or pleural effusion, helps in characterizing the lesion as a true SPN. The current multidetector-row CT scanners that use 16 to 128 detector channels facilitate thin-section (0.6–2.0 mm) analysis of an SPN.[3,5]

Location of the nodule: Some studies have suggested that the location of the lesion in the lung is an independent predictor of the lesion being a malignant SPN. While malignant lesions are more likely to be located in the right lung and in the upper lobes, benign lesions are equally distributed throughout the lung fields.[1,3,5,7] This predilection for the upper lobes, is probably related to the higher concentration of inhaled carcinogens that result from tobacco smoking in the upper lobes.

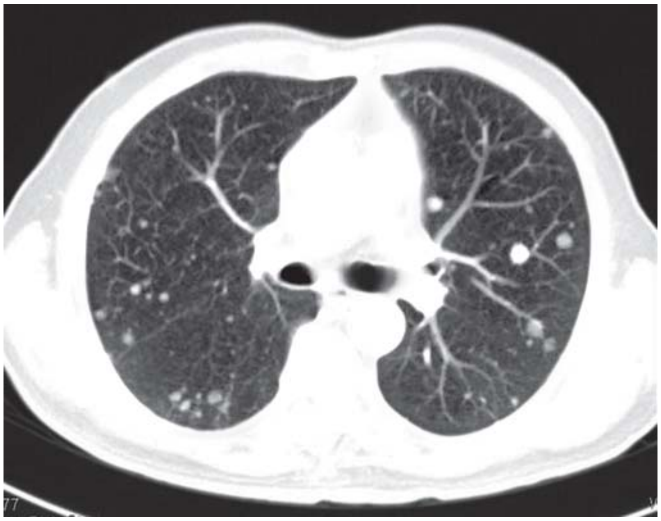


Fig. 120A.2: CT of the chest (lung window) showing bilateral multiple nodules. Further work-up confirmed metastatic malignancy

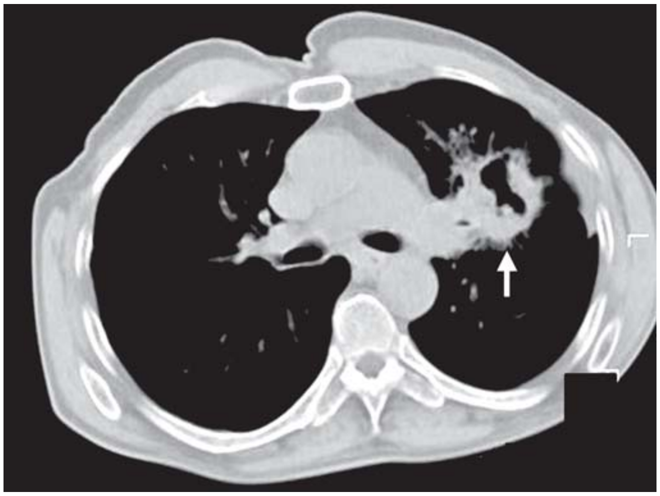

Fig. 120A.3: Non-contrast enhanced CT of the chest (mediastinal window) showing a nodule measuring 41 mm suggestive of a mass lesion. Image-guided biopsy confirmed squamous cell carcinoma of the lung

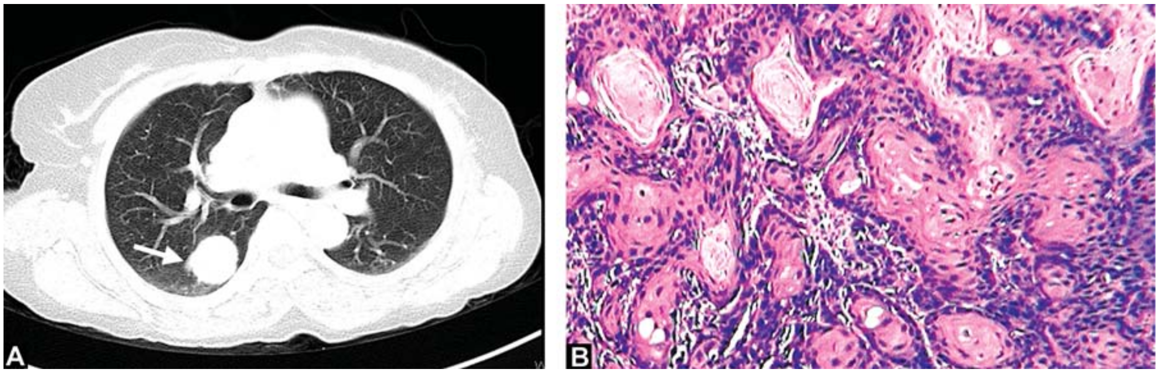
Size: Larger the SPN, higher is the likelihood of malignancy; lesions greater than 3 cm in diameter should be considered malignant until proven otherwise (Fig. 120A.3). The likelihood ratio of malignancy in relation to the size of the SPN as described by Gurney[20] is shown in Table 120A.3.

Shape and margins: Assessment of the shape and margins of the SPN, even though not specific, provides useful clues for categorizing the lesion as benign or malignant.[1,3,5,7] In general, benign SPNs are round in shape and have smooth margins. However, malignant SPNs may rarely present with smooth margins, as in the case of lung cancer (Figs 120A.4A and B), solitary hematogenous metastases

TABLE 120A.3: The likelihood ratio of malignancy in lesions

Size (cm)	*Likelihood ratio*
<1.0	0.52
1.1–2.0	0.74
2.1–3.0	3.7
>3.0	5.2

Data from reference 20



Figs 120A.4A and B: CT of the chest (lung window) showing an SPN with smooth rounded margins (arrow) (A); Photomicrograph of the image guided FNAC was suggestive of squamous cell carcinoma (Papanicolou stain; X 400) (B). (*Courtesy:* Dr KV Sreedhar Babu, Department of Pathology, Sri Venkateswara Institute of Medical Sciences, Tirupati)
SPN = solitary pulmonary nodule; FNAC = fine needle aspiration cytology

from colorectal, renal cell or breast cancer, and peripheral carcinoid tumors. Presence of irregular spiculated margins (corona radiata) is highly suggestive of malignancy. Rarely, irregular margins can be observed even in benign lesions, as in the case of the focal areas of organizing or resolving pneumonia. A lobulated margin is most often seen in hamartomas, but can be observed in malignant conditions, like peripheral carcinoid tumors and adenocarcinomas. Presence of satellite lesions surrounding a larger central nodule is suggestive of a granulomatous disease (e.g. tuberculosis). In pulmonary arteriovenous malformations presenting as an SPN, a feeding and draining pulmonary vessel extending from the hilum of the lung can be evident.

The *comet tail sign* is typically seen in rounded atelactasis and indicates a bundle of curvilinear bronchi and vessels extending into the hilar aspect of a peripherally located SPN that lies adjacent to pleural thickening.[3,5]

Fat: For practical purposes, presence of fat within an SPN with smooth or rounded margins is suggestive of a pulmonary hamartoma; nearly 60% of hamartomas contain fat. Exceptionally rarely, metastases from renal cell carcinoma or liposarcoma presenting as an SPN may show fat.[1,3,5,7]

Ground-glass attenuation: The use of MDCT has facilitated the detection of ''subsolid'' nodules that contain a component of ground-glass attenuation. These may be pure ground-glass SPNs, as well as partly solid lesions consisting of mixed solid and ground-glass lesions, which have been found to have a higher potential for being malignant. Atypical adenomatous hyperplasia, bronchioloalveolar carcinoma and invasive adenocarcinoma can present as subsolid nodules.[1,3,5,7]

The *halo sign* (Figs 120A.5A to D) has been described in invasive *Aspergillus* infection and bronchioloalveolar carcinoma and refers to a poorly defined rim of ground-glass attenuation around the SPN and the halo may represent hemorrhage, tumor infiltration or perinodular inflammation. The *reverse halo sign* (a focal round area of ground-glass attenuation surrounded by a ring of consolidation) has been described in cryptogenic organizing pneumonia and paracoccidioidomycosis.[5]

Calcification: The presence and pattern of calcification within the lesion offers important clues to the etiology of the SPN. Though the chest radiograph is useful in identifying calcification within the SPN, the diagnostic yield is low (sensitivity 50%; specificity 87%).[1,3,5,7] Nearly one-third of the SPNs that do not manifest calcification within the lesion on the chest radiograph, may show calcification on the chest CT.[3] Therefore, non-contrast chest CT (1–3 mm collimation) is considered to be the best technique to identify calcification within an SPN.[3,5] Certain patterns of calcification within the SPN, such as central, laminated, diffuse (Fig. 120A.6), and calcification within a smooth or lobulated nodule are suggestive of a benign lesion, such as a granuloma; popcorn calcification is suggestive of a hamartoma. Rarely, presence of eccentric calcification may be indicative of a calcified granuloma engulfed by a malignancy and amorphous calcification can be present due to dystrophic malignant calcification.

When calcification is not evident in the lesion, CT densitometry can be helpful. With the advent of the modern MDCT, a reference CT phantom is no longer being used and the average attenuation of an SPN can be measured directly. Attenuation values of 200 Hounsfield Units (HU) or greater within a smoothly

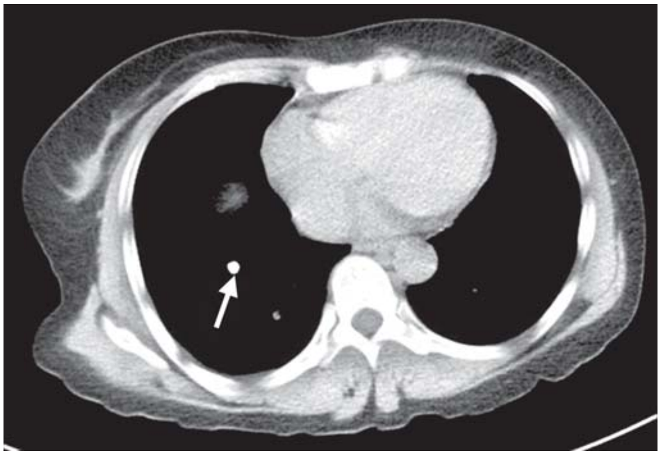

Fig. 120A.6: Non-contrast enhanced CT of the chest (mediastinal window) showing a calcified nodule (arrow)

marginated nodule is considered to be the evidence of microscopic calcification and suggests a benign etiology.[3]

Cavitation: Cavitation can be observed in benign (e.g. abscess, tuberculosis) or malignant (e.g. squamous cell carcinoma) SPNs.[1,3,5,7] However, estimating the cavity wall thickness can be helpful; wall thickness of 5 mm or less suggests a benign lesion, whereas, wall thickness of 15 mm or more is suggestive of a malignant lesion.[1,27]

Other internal characteristics: Detection of cystic or ''bubbly'' lucencies within an SPN (Fig. 120A.7) is highly suggestive of a malignant etiology (e.g. lung cancer, especially adenocarcinomas with bronchioloalveolar cell features). Evidence of air bronchogram within an SPN is suggestive of a malignant etiology (especially bronchioloalveolar carcinoma, rarely pulmonary lymphoma);

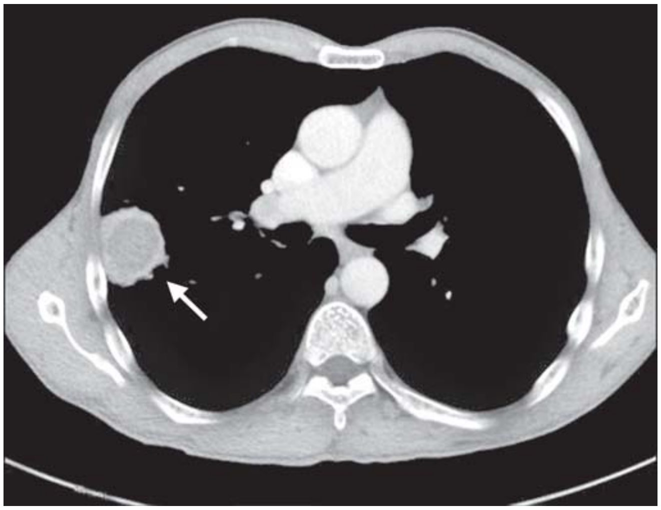

Fig. 120A.7: Contrast enhanced CT of the chest (mediastinal window) showing cystic lucency within the SPN (arrow)

sometimes, benign lesions, such as sarcoidosis and round pneumonia[28,29] may manifest air bronchogram. Presence of subsolid SPNs, in which the nodule has a component of ground-glass attenuation is suggestive of malignancy, especially bronchioloalveolar carcinoma.[1,30]

Contrast enhancement: Contrast enhancement, also called "wash-in" (an increase in the attenuation of a lesion greater than 15 HU after intravenous contrast), of an SPN can help in providing a clue to its etiological origins. The SPNs that enhance less than 15 HU are almost certainly benign (sensitivity 98%, specificity 58%, accuracy 77%).[31] Malignant lesions, by virtue of increased vascularity tend to enhance avidly with the administration of intravenous contrast; typically, malignant SPNs enhance more than 20 (HU).[1,3,31,32] However, benign lesions like active granuloma, hamartoma, arteriovenous malformation, and organizing pneumonia can also manifest in the form of contrast enhancement.[33] Recently "wash-out" or decrease in attenuation over the 15 minutes following contrast injection has also been found to be useful.[5]

Growth: Since, an SPN is assumed to be a sphere and the volume of a sphere is given by the mathematical expression $4\pi r^3/3$ (where r = radius of the sphere) or $\pi d r^3/6$ (where d = diameter), an increase in nodule diameter by 26% corresponds approximately to one doubling in tumor volume. The doubling time can be calculated by using the below mentioned formula:

$dt = (t \times \log 2) / \{3 \times [\log (d2/d1)]\}$,

where

dt = doubling time (days)

t = time in days between the chest radiographs

d2 = diameter of the nodule at the time of the current CT/chest radiograph

d1 = diameter of the nodule at the time of the previous CT/chest radiograph

It has been estimated that the doubling time for majority of malignant nodules is between 20 and 300 days.[34-36] If the SPN has been stable for at least 2 years, it is likely to be benign and usually does not require further evaluation.[1,3,5,7,8, 34-36]

Magnetic Resonance Imaging

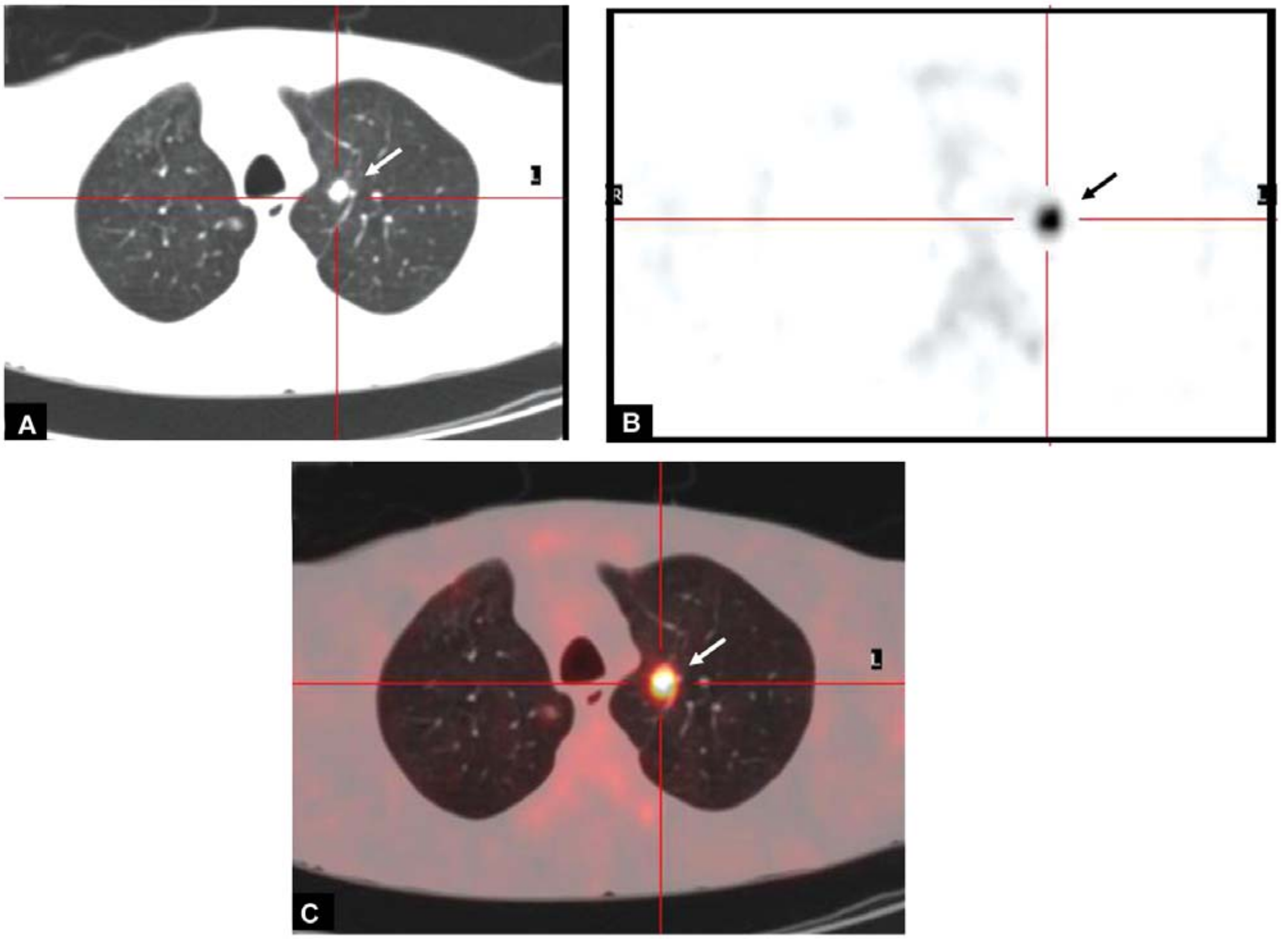
Magnetic Resonance Imaging (MRI), in spite of having the advantage of avoiding ionizing radiation, has been less frequently utilized than MDCT in the evaluation of lung nodules because of its limited spatial resolution, effect of respiratory and cardiac motion on sequences with low temporal resolution. However, Half-Fourier Acquisition Single-Shot Turbo Spin-Echo (HASTE) imaging has emerged as the sequence of choice for MRI of the lungs. This technique facilitates identification of malignant tissues that manifest high signal intensity (due to high T2 relaxivity) against a back-drop of surrounding air-filled, low-signal, lung parenchyma; vessels are identified as flow voids without any apparent signal. For SPNs 5–10 mm in size, HASTE sequence has been found to have a sensitivity of close to 95%.[37, 38]

The different Turbo Spin-Echo (TSE) and 3D gradient-echo [volume interpolated breath-hold (VIBE)] MRI sequences of the lung for detecting pulmonary metastases,[39] the enhancement characteristics of nodules on MRI, such as maximal enhancement ratio and slope of contrast uptake are also being explored as potential imaging modalities for SPNs. These issues merit further study.

Nuclear Medicine Imaging

Positron Emission Tomography CT (PET-CT) (Figs 120A.8A to C) using the radiopharmaceutical 18F labeled 2-deoxy-D-glucose (FDG) has been used to characterize an SPN as malignant or benign.[1,3,5] The FDG standardized uptake value (SUVmax) estimation is used as a semiquantitative method of evaluation of SPNs. In malignant SPNs, metabolism of glucose is typically increased and an SUVmax cut-off of 2.5 has been used to differentiate benign from malignant SPNs.[40]

For SPNs greater than 10 mm in size, FDG-PET has a sensitivity and specificity of 97% and 78% respectively for characterizing it as malignant.[41] However, malignant causes of an SPN, such as a well-differentiated adenocarcinoma of the lung (especially with a bronchiolo-



Figs 120A.8A to C: CT of the chest (lung window) (A), F-18 fluorodeoxyglucose positron emission tomography (FDG-PET) (B) showing an SPN (arrow). PET-CT image of the same patient showing increased uptake in the nodule (arrow)
[*Courtesy:* Dr TC Kalawat, Department of Nuclear Medicine, Sri Venkateswara Institute of Medical Sciences, Tirupati]

alveolar cell carcinoma) and a peripheral carcinoid tumor can produce a false-negative PET-CT result. The PET-CT has a low sensitivity for lesions less than 1 cm in diameter and the use of this technique in this setting is limited; however, if PET-CT results are positive, it would almost certainly prompt biopsy or resection. Common causes resulting in a false-positive PET result include active granulomatous inflammation, focal areas of organizing or resolving pneumonia, and rarely hamartomas.

Computer-aided Diagnosis (CAD)

The CAD techniques have been developed as a method of assisting interpretation by the means of computerized image analysis. The CAD, acting as a second interpreter, facilitates the assessment of nodule size, volume, attenuation, and enhancement characteristics by performing the global analysis of high-resolution MDCT data of the entire nodule. Some reports suggest that CAD may be useful in identifying clinically significant nodules that have been missed by the radiologists.[42-44] Further refinements in CAD, such as the integration of multifunctional CAD platforms into Picture Archiving and Communication Systems (PACS) that provide easy accessibility during reader interpretation may facilitate more widespread use of these techniques.[2] The salient imaging features that facilitate categorization of an SPN as benign is shown in Table 120A.4.

Tissue Sampling Techniques

In spite of the widespread use of various imaging techniques, characterization of some SPNs as benign or

TABLE 120A.4: Radiologic features suggestive of benign and malignant solitary pulmonary nodules

Radiologic feature	*Benign*	*Malignant*
Size of the lesion	Smaller the size of lesion, lesser is the risk of malignancy	Larger the size of lesion, greater is the risk of malignancy
Border	Smooth	Irregular or spiculated (*corona radiata*)
Density	Dense, solid	Nonsolid, ground-glass
Calcification	Concentric, central, popcorn-like, or homogeneous patterns common	Usually noncalcified or eccentric calcification
Satellite lesions	Common in granulomatous lesions	Rare
Wall thickness in a cavity	<5 mm	>15 mm
Doubling time	<1 month; >1 year	1 month to 1 year

malignant is not possible and will warrant tissue sampling and histopathological or cytopathological diagnosis. Various methods, such as image-guided transthoracic Fine Needle Aspiration Cytology (FNAC), needle biopsy, bronchoscopic biopsy with or without electromagnetic navigation systems, Video-Assisted Thoracoscopic Surgery (VATS), or open thoracotomy have been employed for procuring the tissue.[1,3,5,7-9]

Image-guided procedures: Image-guided transthoracic needle FNAC biopsy is frequently used for confirming the etiological diagnosis in patients with SPN in whom the pretest probability of a malignant lesion is high. The test is performed under CT-guidance or ultrasonography guidance (peripherally located or pleural-based lesions). This technique is highly accurate in ascertaining the etiological diagnosis in malignant SPNs (sensitivity >90% for lesions >5 mm in size). Contraindications for transthoracic FNAC and biopsy are an uncooperative patient, presence of a bleeding diathesis, severe bullous emphysema and prior pneumonectomy. Important complications of transthoracic needle biopsy include pneumothorax (seen in 20% of patients) and bleeding, which is usually minor and self-limiting.[1,3,5,7-9]

Video-assisted thoracoscopic surgery: The VATS technique facilitates the procurement of tissue frozen section examination to assist in the decision about whether to proceed with a full lobectomy, especially from peripherally located SPNs and some centrally located SPNs in the lower lobe. Presently VATS offers a lower morbidity and a shorter hospital stay compared with conventional thoracotomy.[1,9,45]

Fiberoptic bronchoscopy: The sensitivity of fiberoptic bronchoscopy (FOB) for detecting a malignant SPN ranges from 10% for SPNs that are less than 1.5 cm diameter) to 40 to 60% for SPNs that are 2–3 cm in diameter. Other factors that influence diagnostic yield of FOB include, its proximity to the bronchial tree and the prevalence of cancer in the given area.[9,46,47]

MANAGEMENT

The management depends on several factors, including the degree of surgical risk, the presence or absence of comorbid conditions, the patient's preferences, and the radiological and surgical capability and expertise available at the center where the patient is being evaluated. The eventual goal is to ascertain the etiological diagnosis so that appropriate therapy can be instituted.

There are no consensus guidelines for the evaluation and management of an incidentally detected SPN. Evidence-based recommendations for the follow-up and management of SPNs incidentally detected based on the American College of Chest Physicians guidelines[7] and the Fleischner Society Guidelines[8] are shown in Figures 120A.9 and 120A.10. A separate algorithm is provided for the evaluation and management of SPNs smaller than 8 mm (Fig. 120A.10) because of the less likelihood of malignancy in lesions that are smaller than 8 mm. These algorithms reflect the current evidence-based guidelines that are available and are likely to evolve as more information becomes available.

Initially, SPNs greater than 8 mm in size should be evaluated on past chest radiographs or CT (if available) to assess the stability of size. If the SPN has been stable for more than two years, such a patient may be may be followed-up without intervention unless morphological features are suggestive of malignancy. For SPNs 8 mm or larger (Fig. 120A.9), patients are categorized based on of low, intermediate and high pretest probability of

cancer. As surgical excision is the definitive treatment for lung cancer, the guidelines,[7,8] recommend a more limited evaluation of patients who are not fit to undergo surgical excision. However, biopsy may still be considered to ascertain the etiological diagnosis in these patients so as to provide appropriate therapy. The evaluation of patients who are fit to undergo lung resection is guided by their pretest probability of a malignant SPN (Fig. 120A.9). The algorithm for lesions smaller than 8 mm (Fig. 120A.10) categorizes the patients into separate treatment groups based on the presence or absence of risk factors for lung cancer. Patients with a low risk for malignancy require less frequent CT follow-up.

CONCLUSION

The goal of evaluating a patient presenting with an SPN is to correctly differentiate malignant SPNs from benign lesions so that appropriate therapy is instituted. The approach to a patient with an SPN is based on the pretest probability of cancer, determined according to the size of the nodule, the presence or absence of risk factors for lung cancer, such as history of tobacco smoking, the patient's age and imaging features of the SPN. When the pretest probability of cancer is low, the nodule should be monitored with serial high-resolution CT. When the probability of cancer is high, diagnostic work-up should be directed to establish the histopathological or cytopathological tissue diagnosis.

Hematopoietic and Lymphoid Neoplasm of Lungs

Pankaj Malhotra

INTRODUCTION

Lungs can be involved in several lymphohematopoietic neoplasms, either primarily or secondarily.[1-4] In primary lung involvement, the diagnosis is usually not suspected and it is the cytology or biopsy of the resected tissue that gives first clue to the diagnosis. Lung involvement in secondary neoplasms is not uncommon; however, again the proof comes by Broncheoalveolar Lavage (BAL) fluid analysis/histopathology of the mass because the differential diagnosis includes infections that are far more common than the lung involvement by neoplasms. After the diagnosis, the work-up of these patients is fairly standardized. The prognosis depends upon several factors such as the age of the patient, duration of symptoms, performance status of patient, comorbidities and staging of the disease.

The lungs can suffer not because of lymphoma per se but also due to side effects of the systemic chemotherapy or radiotherapy to treat lymphomas.[5-7] Lastly, it is important to know about the lung functions at baseline before instituting chemotherapy or radiotherapy because some anti-neoplastic drugs require modification in presence of lung dysfunction.

LYMPHOMAS

Lymphomas are diverse groups of neoplastic disorders primarily known to have their origin from the lymphnodes.[8] They are generally classified as Hodgkin's Lymphoma (HL) and non-Hodgkin's Lymphoma (NHL) based on the histopathology and immunohistochemistry of the involved tissue or mass. NHL constitutes approximately 80 to 85% of all lymphomas. The treatment and prognosis is different in both lymphomas and hence it is important to differentiate the two entities. Most lymphomas origin from the lymph nodes (nodal lymphomas), but they can arise from lymphatic tissue present in organs other than lymph nodes, labeled as extranodal. Primary involvement of the lungs (trachea, bronchus, lung parenchyma) is rare accounting for less than 1% of all extranodal lymphomas.[2-3] However, involvement of the mediastinal group of lymph nodes is quiet common.

Lymphomas are usually systemic diseases and definition of primary and secondary involvement of body site is sometimes arbitrary in nature. When lymphomas present for the first time in the tracheobronchial tree or lung parenchyma and these sites have major disease load, they are called primary lymphomas of the lungs.[1-4] When the bulk of the disease lies in other organs along with lymphomatous involvement of the lungs, this is classified as secondary lung involvement.[9,10] The secondary involvement of the lungs can occur either through circulation or spread from neighboring sites (Fig. 120B.1). Even though the definition is somewhat arbitrary, it is important to classify the involvement because it has therapeutic and prognostic implications (vide infra).

For purpose of simplification both lymphomas are discussed separately, but for a few general considerations. The diagnostic work-up for both HL and NHL is similar as discussed below:

General Considerations

Lymphomas usually have their origin from the lymph nodes or lymphoid follicles present in the organ.[8] The

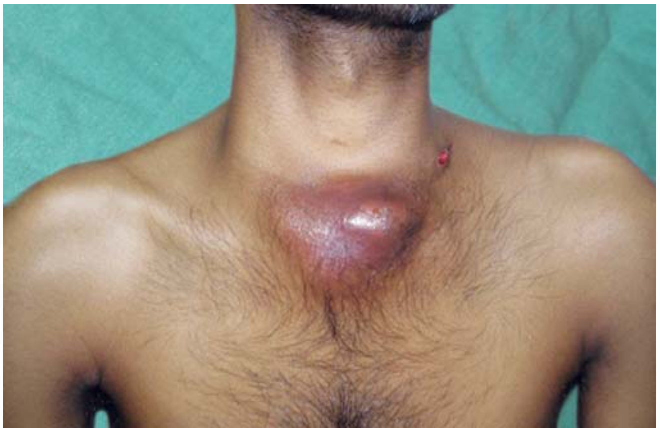

Fig. 120B.1: Hodgkin's lymphoma presenting as chest wall mass in a 22-year-old gentleman

duration of symptoms can vary from weeks, months and sometimes years depending upon the aggressiveness of the disease. Younger age is generally associated with more aggressive disease while both low-grade and high-grade presentations of lymphomas are common as age advances.[8] The systemic symptoms such as fever, weight loss and night sweats, if present classify the patient into category B while their absence is denoted as A. Similarly, the extranodal site involvement by lymphoma is categorized and written as E. Involvement of spleen is considered as nodal and depicted as S. Tumor mass of size more than 10 cm is labeled as X. Thus, a patient with primary NHL of the lung with size of 14 cm without systemic symptoms would be labeled as Primary NHL Lung, stage 1EX A.

Any mass of more than 10 cm generally requires local radiotherapy after the completion of chemotherapy. The diagnosis of lymphoma requires a proper categorization of lymphoma into the most recent WHO classification of hematopoietic and lymphoid neoplasms.[11] WHO classification of lymphomas is based on the morphology of lymphoma (B, T and NK cell lineage), immunophenotyping, chromosomal and molecular characteristics (Table 120B.1).

Once the diagnosis of lymphoma is made, proper staging is required. Staging of both HL and NHL is done by Ann Arbor (Table 120B.2). Detailed investigations are required for proper work-up of patient with lymphoma (Table 120B.3). The staging helps in prognostication as well as making therapeutic decisions whether only chemotherapy, only radiotherapy or both chemotherapy and radiotherapy, is required. Rarely, the surgery may be curative in localized lymphoma of the lung parenchyma when complete resection of the lesion is possible.

Prognosis of NHL is defined by International Prognostic Index (IPI).[12] This is based on age, stage of the disease, LDH, performance status of the patient and extranodal site involvement (Table 120B.4). The higher the stage, the bad is the prognosis. There is a similar prognostic score for HL also based on hemoglobin, WBC count, age, stage, serum albumin and lymphocytopenia. While on treatment, nonresponsiveness to 1–2 cycles of chemotherapy is probably the most important adverse feature. The response criteria to systemic chemotherapy are now fairly standardized (Table 120B.5).[13]

Overview of Primary Lung Involvement by Lymphomas

Introduction

Involvement of tracheobronchial tree and lung parenchyma by lymphomas without involvement of adjacent lymph nodes or other structures is quiet rare. The diagnosis requires demonstration of clonal lymphoid proliferation in the lung parenchyma, trachea or bronchi without detectable involvement of extrapulmonary sites at diagnosis and during the subsequent three months.[1-4]

Epidemiology

Due to rarity of these cases, epidemiology of primary NHL and HL is difficult to comment, however, they account for less than 1% of all extranodal lymphomas. From the isolated case report and series, it appears that most cases are reported in the middle age and older age group.[14-20] In some series, female population predominate. Systemic symptoms (B symptoms) are more common at presentation. There are no known risk factors for the development of these lymphomas except for the low-grade primary NHL of lung (MALT lymphomas, discussed below).

Presentation

Patients can usually present with persistent cough, hemoptysis, dyspnea, wheezing, chest pain, or discomfort or stridor. Patient may have fever, weight loss and night sweats (B symptoms). Chest skiagram is usually the first investigation that is required in these patients. This may show the presence of nodule, mass, atelectasis, cavitation or other shadow.[21-24] The differential diagnosis consists of infectious diseases (tuberculosis, histoplasmosis) or noninfectious diseases (Sarcoidosis, Wegener's granulomatosis).[25-27] Sometimes, both lymphoma and infectious process may coexist in the lung and hence a biopsy is a must in these cases.

TABLE 120B.1: WHO classification of lymphomas

Precursor B-cell neoplasm

Precursor B-lymphoblastic leukemia/lymphoma (precursor B-cell acute lymphoblastic leukemia)

Mature (peripheral) B-cell neoplasms

- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- B-cell prolymphocytic leukemia
- Splenic marginal zone lymphoma
- Hairy cell leukemia
- Splenic lymphoma/leukemia, unclassifiable
- Lymphoplasmacytic lymphoma
- Heavy chain diseases
- Plasma cell neoplasms
- Extranodal marginal zone lymphoma of mucosa associated lymphoid tissue (MALT lymphoma)
- Nodal marginal zone lymphoma
- Follicular lymphoma
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma
- T-cell/histiocytic-rich large B-cell lymphoma
- Primary DLBCL of the CNS
- Primary cutaneous DLBCL, leg type
- EBV positive DLBCL of the elderly
- DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK positive large B-cell lymphoma
- Plasmablastic lymphoma
- Large B-cell lymphoma arising in HHV 8-assocaited multicentric Castleman disease
- Primary effusion lymphoma
- Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin's lymphoma

T-cell and NK-cell neoplasms

Precursor T-cell neoplasm

Precursor T-lymphoblastic lymphoma/leukemia (precursor T-cell acute lymphoblastic leukemia)

Mature (peripheral) T/NK-cell neoplasms

- T-cell prolymphocytic leukemia
- T-cell granular lymphocytic leukemia
- Chronic lymphoproliferative disorders of NK cells
- Aggressive NK-cell leukemia
- EBV-positive T-cell lymphoproliferative disorders of childhood
- Adult T-cell lymphoma/leukemia
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy associated T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis like T-cell lymphoma
- Mycosis fungoides
- Sèzary syndrome
- Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
- Primary cutaneous gamma-delta T-cell lymphomas
- Peripheral T-cell lymphoma, NOS
- Angioimmunoblastic T-cell lymphoma
- Anaplastic large cell lymphoma (ALCL), ALK positive
- Anaplastic large cell lymphoma (ALCL), ALK negative

Immunodeficiency-associated lymphoproliferative disorders

- Lymphoproliferative diseases associated with primary immune disorders
- Lymphomas associated with HIV infection
- Post-transplant lymphoproliferative disorders
- Other iatrogenic immunodeficiency-associated lymphoproliferative disorders

Histiocytic and dendritic cell neoplasms

- Histiocytic sarcoma
- Tumors derived from Langerhans cells
- Interdigitating dendritic cell sarcoma
- Follicular dendritic cell sarcoma
- Other rare dendritic cell tumors
- Disseminated juvenile xanthogranuloma

Hodgkin's lymphoma

- Nodular lymphocyte predominant Hodgkin lymphoma
- Classical Hodgkin Lymphoma
  Nodular sclerosis classical Hodgkin's lymphoma
  Mixed cellularity classical Hodgkin's lymphoma
  Lymphocyte-rich classical Hodgkin's lymphoma
  Lymphocyte-depleted classical Hodgkin's lymphoma

TABLE 120B.2: Ann Arbor staging of lymphomas

Stage I: Involvement of a single lymph node or of a single extranodal organ or site (IE)

Stage II: Involvement of two or more lymph node regions on the same side of the diaphragm, or localized involvement of an extranodal site or organ (II E) and one or more lymph node regions on the same side of the diaphragm

Stage III: Involvement of lymph node regions on both sides of the diaphragm, which may be accompanied by localized involvement of an extranodal organ or site (III E) or spleen (III S) or both (III SE)

Stage IV: Diffuse or disseminated involvement of one or more distant extranodal organs with or without associated lymph node involvement

1. Fever >38°C, night sweats and weight loss >10% of body weight in the last six months of diagnosis are defined as systemic symptoms (presence of any one systemic symptom is defined as B symptoms whereas absence of all three symptoms is defined as A in the staging system)
2. Spleen involvement is considered as nodal

TABLE 120B.3: Work-up of a lymphoma patient

1. Lymph node biopsy (excisional or core) with immunohistochemistry
2. CECT neck/chest/abdomen including pelvis
3. Complete blood counts, ESR and bone marrow examination (aspiration and trephine biopsy)
4. Biochemical (Urea, creatinine, uric acid, calcium, phosphorus, bilirubin, SGOT, SGPT, alkaline phosphatase, blood sugar)
5. EKG, echocardiography or MUGA scan
6. Urine examination
7. Serum LDH, Serum β2 microglobulin
8. HbsAg, Anti HCV, HIV
9. PET CT scan

Work-up in resource constraints settings
Chest X-ray and ultrasound abdomen instead of CT or PET CT scan

TABLE 120B.4: International prognostic Index for on-Hodgkin's lymphoma

One point is assigned for each of the following risk factors:

- Age greater than 60 years
- Ann Arbor Stage III or IV disease
- Serum lactate dehydrogenase more than normal
- ECOG performance status of 2 or more than 2
- Involvement of more than one extranodal site

Risk group	*Number of factors*
• Low	0, 1
• Low intermediate	2
• High intermediate	3
• High	4, 5

TABLE 120B.5: Response definitions in NHL

Response	*Definition*	*Nodal masses*	*Spleen, liver*	*Bone marrow*
CR	Disappearance of all evidence of disease	(a) FDG-avid or PET positive prior to therapy; mass of any size permitted if PET negative (b) Variably FDG-avid or PET negative; regression to normal size on CT	Not palpable, nodules disappeared	Infiltrate cleared on repeat biopsy; if indeterminate by morphology
PR	Regression of measurable disease and no new sites	>/= 50% decrease in SPD of up to six largest dominant masses; no increase in size of other nodes (a) FDG-avid or PET positive prior to therapy; one or more PET positive at previously involved site (b) Variably FDG-avid or PET negative; regression on CT	>/= 50% decrease in SPD of nodules (for single nodule in greatest transverse diameter); no increase in size of liver or spleen	Irrelevant if positive prior to therapy; cell type should be specified
SD	Failure to attain CR/PR or PD	(a) FDG-avid or PET positive prior to therapy; PET positive at prior sites of disease and no new sites on CT or PET (b) Variably FDG-avid or PET negative; no change in size of previous lesions on CT		
Relapsed disease or PD	Any new lesion or increase by >/= 50% of previously involved sites from nadir	Appearance of a new lesion(s) >1.5 cm in any axis, >/=50% increase in SPD of more than one node, or >/=50% increase in longest diameter of a previously identified node > 1 cm in short axis Lesions PET positive if FDG-avid lymphoma or PET positive prior to therapy	>50% increase from nadir in the SPD of any previous lesions	New or recurrent involvement lesions

Abbreviations: CR, complete remission; FDG, [18F] fluorodeoxyglucose; PET, positron emission tomography; CT, computed tomography; PR, partial remission; SPD, sum of the product of the diameters; SD, stable disease; PD, progressive disease.

Diagnosis

Sputum examination for malignant cytology sometimes can give a clue to the diagnosis. The usual investigations that are carried out are bronchoscopy and transbronchial lung biopsy, or open lung biopsy. An adequate tissue specimen is the first and foremost requirement.[28-31] Morphology along with immunochemical stains and rarely molecular analysis from the tissue specimen will clinch the diagnosis. If adequate tissue specimen is not possible, sometimes cytology with immunocytochemistry can suggest and confirm the diagnosis.

Treatment and Outcome

Patients who present with obstructive endobronchial lesions require rigid bronchoscopy and stenting.[32,33] Sometimes laser therapy with Neodymium: Yttrium-Aluminum Garnet Laser (Nd:YAG) or Photodynamic Laser Therapy (PDT) has been used in these life-threatening obstructive lesions. In earlier case reports and case series, surgery alone or surgery followed by radiotherapy was used with good results.[34] Lately, chemotherapy is used more frequently in primary lymphomas of the lungs because of the adverse long-term side effects of radiotherapy given to lung parenchyma. The principle of treatment varies according to the histology as well as to the burden/staging of the lymphoma.[35]

Secondary Lung Involvement in Hodgkin's Lymphoma

The mediastinal lymph nodes are involved in almost two third patients with HL,[21] while the lung parenchymal involvement occurs in 10% of patients, which is usually the extension from the involved lymphnodes.[22] The most common histological type of HL is the nodular sclerosis variety. If the mediastinal lymphadenopathy is more than one-third the size of the internal thoracic diameter, it is defined as bulky disease and these patients are candidates for mediastinal radiation after the chemotherapy. In order of decreasing frequency, the nodes involved are in the anterior mediastinum, paratracheal, hilar, subcarinal, peridiaphragmatic, paraesophageal and internal mammary nodes.[22] The extension into the lung parenchyma occurs in the form of interstitial linear infiltrates or small nodules. If this extension is in direct continuity of the involved lymph nodes, a separate procedure to document lung involvement by HL may not be necessary.[24] In many cases, these lesions may occur because of an infectious process and hence if possible, fine needle aspiration, bronchial lavage or rarely an open biopsy may be required for documentation.

HL is considered as one of the curable malignancy depending upon the stage of the disease.[8] Hence, it is very important to know the stage of the disease before administration of chemotherapy. HL is also very sensitive to radiation therapy. The treatment of HL has evolved from only radiotherapy to chemotherapy alone or combination of both chemotherapy and radiotherapy. As a general rule, in the stage I and II disease, 2–4 cycles of chemotherapy (ABVD) followed by radiotherapy are generally used. Stage III and IV HL is usually treated by chemotherapy alone. However, at any stage if the bulky disease is present at baseline (defined as tumor size more than 10 cm), radiotherapy is always combined with chemotherapy.

HL with secondary lung involvement is treated initially with chemotherapy to reduce the size of tumor since radiation injures the lung parenchyma. Bleomycin included in the treatment protocol (ABVD) is also toxic to lung and thus these patients should be monitored closely with pulmonary function tests. In females, who receive mediastinal radiation to treat their HL, the future development of breast carcinoma is also high, thus these patients require monitoring by regular mammography, generally starting at least five years prior to the recommended age of screening in general patients.[8]

Primary Lung Involvement in Non-Hodgkin's Lymphoma

The involvement of lymph nodes in NHL is generally noncontiguous (as opposed to contiguous spread in HL).[8] The involvement of the lungs can occur in up to 40% patients of NHL. NHL's are usually graded into low-grade and high-grade types. The most common variety of low-grade lymphoma is mucosa associated lymphoid tissue (MALT) while diffuse large B-cell and lymphoblastic lymphoma are the common high-grade lymphomas involving the lungs. The treatment and prognosis is different for low-grade and high-grade NHL, hence they are separately discussed below.

MALT Lymphoma

The most common type of primary pulmonary lymphoma is related to bronchus-associated lymphoid tissue clonal proliferation and is grouped under the category of mucosa associated lymphoid tissue lymphoma.[36-38] These are low-grade B-lineage NHL with primary origin in the lymphoid tissue present in the bronchus or lung parenchyma and is due to the prolonged antigenic stimulation of any cause. This is akin to gastrointestinal MALT lymphomas which occur mostly due to persistent antigenic stimulation

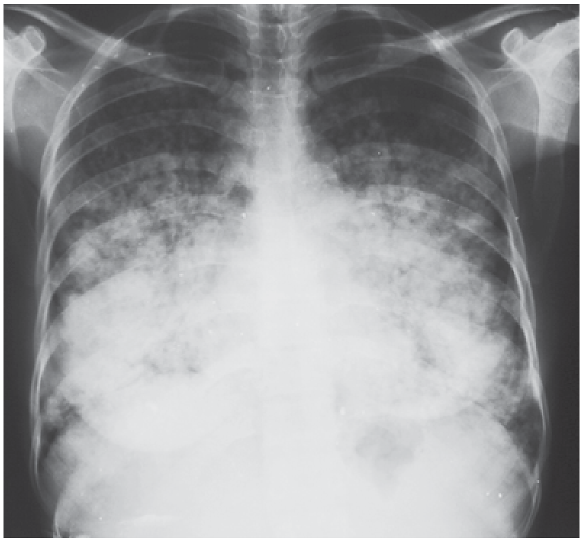

Fig. 120B.2: Mucosa associated lymphoid tissue lymphoma presentation in a 40-year old lady

caused by *Helicobacter pylori* infection. However, in the lung parenchyma, no single organism has been identified and at present cause of MALT lymphoma of the lung is attributed either due to the recurrent infections or due to autoimmune/rheumatological disorders of the body.[39-42] Patients may be asymptomatic and lesions are detected on routine chest skiagram or they may have nonspecific chest symptoms that may occur due to other causes (Fig. 120B.2).[42] Due to rarity of these lymphomas, it is mostly on histology and immunohistochemistry on resected tissue that the diagnosis is made. In approximately 25% of patients, MALT lymphoma can present simultaneously at other sites such as the orbit, the salivary glands and the bone marrow. The differential diagnosis consists of other lung conditions in which lymphocyte proliferation occurs such as follicular hyperplasia, lymphocytic interstitial pneumonia (usually bilateral) or hypersensitivity pneumonitis. Sometimes, the molecular techniques are required to accurately make the diagnosis of MALT lymphoma. These lymphomas when present for a very long period of time, can transform into a high-grade variety with systemic symptoms.

Low-grade lymphomas are considered incurable and hence treatment is instituted only when the disease is symptomatic or progressive. Mostly, these lymphomas get treated either with single agent chemotherapy like chlorambucil, cyclophosphamide, deaminase inhibitors, monoclonal CD20 positive antibody or combination of these.[8] The final treatment decision is taken based on the stage of the disease, age and performance status of the patient. Rarely, surgery alone or combined with radiotherapy is considered in these cases. The responses are excellent, but the disease tends to come back after some time.[41]

Secondary Involvement of Lungs by High-grade NHL

High-grade NHL generally presents with large mediastinal masses. The most common types are Precursor T-cell lymphoblastic lymphoma/leukemia and primary mediastinal large B-cell lymphoma.

Primary Mediastinal Large Cell Lymphoma

Primary mediastinal large B-cell lymphoma is a specific entity in WHO classification of lymphoma.[11] They arise from thymus and constitute 2–3% of all NHL. They have slight female preponderance and usually present in younger age groups.[43-45] Most presenting symptoms occur because of a rapidly enlarging mediastinal mass compressing various mediastinal structures. The rapidly enlarging mass can infiltrate into the adjacent lung parenchyma, chest wall, pleura and pericardium. Thus, the presenting symptoms can be cough, hoarseness of voice, chest pain and dyspnea. Systemic B symptoms are present in one fifth of patients. The work-up of these patients is the same as for other high-grade NHL. Mediastinal lymph node core biopsy either ultrasound guided, endoscopic guided or by thoracoscopy is required to accurately classify this condition. The treatment is similar to that for other diffuse large B-cell lymphoma (RCHOP) though many physicians treat with third generation chemotherapy regimens.[43] Most patients do require radiotherapy; postchemotherapy as the mediastinal mass is usually more than 10 cm at presentation. If the treatment is initiated early, the response rates are similar to those seen with diffuse large B-cell lymphoma at other sites (60 to 70% depending upon the IPI).

Precursor T-cell Leukemia/Lymphoma

In the WHO classification of lymphohematopoietic disorders, the distinction between high grade lymphoma and leukemia has not been made because the treatment of both conditions is similar.[11] T-cell lymphoma/leukemia usually presents with large mediastinal mass in young males and generally carries poor prognosis. The presenting symptoms occur because of rapidly enlarging mediastinal mass compressing on the adjacent structures. In most cases, the disease is associated with HTLV-1 infection. The treatment is done with intensive chemotherapy, and in many cases allogeneic stem cell transplantation may be required afterwards.

LYMPHOMATOID GRANULOMATOSIS (LYG)

This is another condition which can be confused with various malignant as well nonmalignant disorders of the lung.[8] The cause of this condition is unknown but it is mostly present in patients with immunological abnormalities. The disease is characterized by lung nodules or masses mostly in the lower lobes or periphery of the lung fields.[1] In a substantial number of patients, central nervous system abnormalities in the form of seizures or focal deficit and dermatological involvement in the form of erythematous skin rashes, skin nodules or ulcers can occur. The disorder has been described as akin to post-transplant lymphoproliferative disorder. The disease usually presents in the middle to elderly age population and the usual symptoms are cough, hemoptysis and dyspnea.

The diagnosis is always made from surgical biopsy of the resected nodule or mass. Wegener's granulomatosis and T-cell lymphoma constitute the close differential diagnoses. Similar to WG, there is a granuloma formation but the cells are atypical, immature and most B-cell show infectivity with Epstein-Barr Virus (EBV). Similar to T-cell lymphoma, the granulomas are surrounded by abundant reactive T-cells, but there is absence of cytopenias and paraproteinemias, usually seen in T-cell lymphomas. LYG histologically is further graded into three types depending upon the number of cells infected with EBV. The aggressiveness of the disease increases as the histological grade increases from one to three. The treatment thus also varies depending upon the histological grade. Histological grade one and sometimes two can be observed without any treatment whereas grade three LYG always require treatment, usually akin to that for patients with diffuse large B-cell lymphoma.[8]

SECONDARY INVOLVEMENT OF LUNG BY OTHER SYSTEMIC HEMATOPOIETIC AND LYMPHOID DISORDERS[46-48]

Most malignant hematopoietic and lymphoid disorders are systemic in nature and the lungs are secondarily involved. This section will cover those disorders which have not been covered above.

Castleman Disease[46]

Castleman disease (angiofollicular lymph node hyperplasia) was first described in 1954 as a benign localized mass of lymph nodes in the mediastinum. Later on, additional types of this condition were recognized. The disease can be unicentric or multicentric, divided histologically into hyaline-vascular variant and plasma cell variant.

Unicentric CD present like a single mass lesion that can present in the mediastinum, pleura, chest wall and rarely in the lungs. Mostly young adults and middle-aged individuals are affected. The disease is mostly asymptomatic unless it presses on some of the important nerves or vessels. Resection of the mass is curable in these patients. No treatment is required If the disease is asymptomatic. Prevalence of unicentric plasma cell variant is rare than the multicentric plasma cell variant. Multicentric plasma cell variant usually presents in the middle age to elderly age group. The disease has become more common in the presence of HIV infection. The lesions can occur in the mediastinum, lungs and various extrathoracic and retroperitoneal regions. Systemic symptoms such as fever, weight loss and fatigue are usually present in most of the patients. In many instances, the disease has been linked to the presence of human herpes virus 8 infections that can be demonstrated in the resected tissue specimen. Patients with multicentric Castleman disease require treatment in the form of systemic chemotherapy. If it is associated with HIV infection, antiretroviral therapy should be instituted as soon as possible though sometimes the flare up of the disease is known. Unicentric Castleman disease is generally curable with the surgical resection.

Plasma Cell Dyscrasias[47, 48]

Plasma cell dyscrasias comprise a variety of disorders such as monoclonal gammopathy of unknown significance, multiple myeloma, Waldenström's macroglobulinemia and primary amyloidosis. All these disorders are characterized by neoplastic proliferation of immunoglobulin producing plasma cells. Lungs are secondarily involved in the disease process. The manifestations in the lungs occur in the form of parenchymal nodules or interstitial infiltrates. The diagnosis is made from other systemic features demonstrating the clonal proliferation of plasma cells in the form of monoclonal band in the serum or urine. Lung biopsy is often required to rule out involvement by an infectious disease. The treatment is directed towards the systemic disease. Major lung involvement is associated with poor prognosis.

Post-transplant Lymphoproliferative Disorders (PTLDs)

Lymphoproliferative disorders developing after organ transplantation is considered as a distinct entity with a prevalence rate of up to 20% in different series.[11] Their spectrum ranges from benign polyclonal lymphoproliferation to malignant lymphomas. Most disorders occur during the first year after transplantation.[49] Epstein -Barr virus infection acquired post-transplant is one of the important risk factor besides the degree of immunosuppression. There is some variation in the prevalence of PTLDs following different organ transplantation. The risk is probably greater among post lung and heart transplantation because the degree of immunosuppression is higher.

Intrathoracic presentation of PTLD occurs in up to 29% patients.[50] The presentation is mostly in the form of lung nodules; patch airspace disease and mediastinal lymphadenopathy. The differential diagnosis revolves around infectious diseases that can occur in patients on immunosuppression; hence a surgical biopsy of the lesion or image guided biopsy from the intrathoracic lymph node is mandatory. More than 90% of the lesions show positivity with EBV infection. Initial treatment consists of reduction in immunosuppression that probably works only in early lesions. In advanced lesions combination chemotherapy is the treatment of choice.[51] The prognosis depends upon multiple factors such as the stage and the grade of the lesion, transplanted organ function and performance status of the patient. The mortality is usually high reaching up to 50% in some of the series.

Chemotherapeutic Drugs Lung Toxicity

Use of antineoplastic drugs can result in lung toxicity which is very difficult to distinguish from infectious diseases that occur in patients with hematological malignancies.[52] However, lung toxicity of anti-cancer drugs is a known complication.[7] Lung involvement can present with nonspecific interstitial pneumonitis, organizing pneumonia, desquamative interstitial pneumonia, eosinophilic pneumonia, granulomatous pneumonitis, diffuse alveolar hemorrhage, retinoic acid syndrome, noncardiogenic pulmonary edema and acute respiratory distress syndrome.[52-58] The classes of drugs involved in causation of these symptoms are anthracyclines, purine analogs, anti-angiogenesis drugs, monoclonal antibodies, proteosome inhibitor, alkylating agents, antibiotics, arsenic trioxide and all transretinoic acid, to name a few. The respiratory symptoms appear usually 2–14 days after the start of the offending drug. Most patients are initially treated for infectious complications which are far more common than the drug toxicity. However, the index of suspicion should be kept high in patients where no infectious agents are identified and temporal correlation of symptoms is related to the administration of the drugs.[7] The distinction between the two entities would lead to administration of corticosteroids in drug induced toxicity with gratifying results.

PYOTHORAX ASSOCIATED LYMPHOMAS

As the name suggests, lymphoma that develop in chronic pyothorax cavity are labeled as pyothorax associated lymphoma. This entity was first described in Japan in 1987 when the authors noted development of lymphoma among patients who were treated with artificial pneumothorax as a treatment of their pulmonary tuberculosis some 30–67 years back.[59,60] The postulation put forward by authors was that chronic long-standing inflammation in the pleura was responsible for the development of this lymphoma. The hypothesis is similar to what has been given for the development of MALT lymphoma developing at other sites. Further research into this type of lymphoma suggested association of Epstein-Barr virus infection. Hence, almost all pyothorax associated lymphomas are associated with B-lineage mostly due to diffuse large B-cell type of lymphoma.[61,62]

The median age of patients at the time of presentation is above 70 years and generally patients have other comorbidities. The presenting symptoms are pain in the chest or the back along with systemic symptoms such as the fever and the weight loss. Chest skiagram is usually the first investigation followed by either CT or MRI scans. The differential diagnosis includes other chest tumors such as the mesothelioma, and the lung carcinoma. The diagnosis is achieved by performing a core biopsy of the mass and with immunohistochemistry.[63] Further, staging of lymphoma is done as mentioned earlier. Bone marrow involvement by lymphoma is rare. The treatment is given with chemotherapy as used for other large B-cell lymphoma. Sometimes, radiation is required if the tumor does not resolve completely after the chemotherapy. The prognosis is dismal in most cases because of the presence of comorbidities.[64]

Mediastinal Disorders

Arjun Srinivasan, SK Jindal

INTRODUCTION

Mediastinum is thoracic cavity which lies between the lungs. It is bound laterally by the parietal pleurae, anteriorly by the sternum, posteriorly by the vertebral column and paravertebral gutters, superiorly by the thoracic inlet and inferiorly by the diaphragm. Interest in mediastinum stems from myriad of vital structures it encloses (Table 121.1) and their associated diseases with classical clinical, as well as radiological presentations. The lack of distinct anatomical planes between compartments, similar clinical manifestations due to spectrum of diseases, and relative inaccessibility of the structures make evaluation of mediastinal disorders a daunting task.

After a brief overview of anatomy and relevant radiological investigations, specific disorders will be discussed with emphasis on clinical manifestations and disease management.

The Mediastinal Anatomy and Compartments

Subdivision of mediastinum has been attempted by clinicians, radiologists and surgeons resulting in numerous classifications and resultant confusion. Classification proposed by Shields in 1972 divides mediastinum into three compartments; anterior, middle (visceral) and posterior (paravertebral sulcus). This is simple and useful classification, as further subdivisions in the absence of distinct anatomical planes are redundant because neither disease nor air can be contained within the compartments. The only resistance to spread of either is the mediastinal pleural reflections laterally; superior communication with neck and inferiorly with retroperitoneum ensures free dissemination. The boundaries of anterior compartment are the sternum, the first rib and an imaginary curved line following the anterior heart border and brachiocephalic vessels from the diaphragm to the thoracic inlet. The middle (visceral) compartment extends from the posterior limit of the

TABLE 121.1: Contents of mediastinal compartments

Anterior	*Middle*	*Posterior*
Pericardial fat	Heart and Pericardium	Azygous and hemizygous veins
Thymus gland	Trachea, main bronchus and Hila	Esophagus
Substernal extensions of thyroid and parathyroid glands	Innominate veins and superior vena cava Aortic arch and great vessels Phrenic and vagus nerves	Azygous and hemizygous veins Descending aorta Sympathetic trunk
Lymph nodes	Lymph nodes	Intercostal nerves Thoracic duct
Connective tissue	Connective tissue	Connective tissue

anterior compartment to the anterior surface of the vertebral columns and then to the thoracic inlet. The posterior compartment (paravertebral sulcus) extends from the anterior surface of the vertebral column to the anterior surface of the paravertebral ribs.

Lymphatics

As with the compartments of mediastinum, the lymphatics are interconnected and involvement of adjacent stations is extremely common in disease. Separation to distinct stations forms the cornerstone in the management of bronchogenic carcinoma. Naruke's division into 14 stations is widely used for this purpose.

IMAGING OF MEDIASTINUM

Conventional Chest Radiograph

Conventional chest radiograph is the first step in the evaluation of any chest symptom and mediastinal disease is no different. In fact, as many as 40% of mediastinal masses may be detected during routine chest radiograph.[1] Radiographs with posteroanterior (PA) and laterolateral (LL) views represent the basic imaging modality in the study of the chest and mediastinum. Chest radiography allows localization of the pathological process; orthogonal projections can demonstrate site, size and density and the presence of calcifications, thereby narrowing the range of differential diagnoses. Additional views (oblique or lordotic) may be useful for distinguishing true images from composition images. Moreover, fluoroscopic examination and opacification of the esophagus will provide valuable complementary information.

Radiologically, a line is formed when certain conditions are met. There is a difference in density between two adjacent tissues; the two tissues are separated by a curved surface; the beam hits this surface tangentially. These conditions occur often in chest radiography where the reflections of the lungs (ventilated and therefore radiolucent) on the mediastinum (radiopaque) form several "lines", known as mediastinal lines. If the line has a double interface (air-mediastinum-air), it may be called a "stripe".[2] In the anterior mediastinum, PA view reveals the anterior junction line and lateral view, the retrosternal line.[3] Normal morphology of these lines is a reliable indication of normality of the single mediastinal compartments; the presence of space-occupying lesions will cause their displacement, distortion or cancellation. Mass may on the other hand be plainly visible protruding from either side of mediastinum. Chest radiography is almost always able to indicate the presence and site of mediastinal disease, but apart from a few exceptions, it cannot define its nature, organ of origin or the presence of possible infiltrative features. Further investigations are therefore needed to characterize the disease.

Computerized Tomography (CT)

Axial imaging avoids the problem of overlapping tissues with similar density: Demonstration of mediastinal spaces with their lymph nodes, relation with surrounding structures and blood vessels represent the most important contributions of CT. Indications include characterization of lesions previously identified on standard X-ray and assessment of the mediastinum in patients with a clinical suspicion of disease but negative X-ray.[4,5] Improved resolution ensures better delineation of structures including point of origin, extension and relation to adjacent organs. This also helps in directing diagnostic procedures like fine needle aspiration or biopsy.

Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging is used less frequently compared with CT in the evaluation of mediastinal masses, mainly because of its limited availability and higher cost; however, MRI has a capacity for multiplanar imaging and the ability to image vessels, and it can provide better tissue characterization than CT. Additionally, MRI is excellent in the evaluation of regions of complex anatomy such as the thoracic inlet, the perihilar, paracardiac and peridiaphragmatic regions, and for the assessment of posterior mediastinal or paravertebral masses.[6]

Ultrasonography

Traditional ultrasonography (US) has role in evaluation of anterior mediastinal masses in children, especially thymic masses. Esophageal ultrasonography (EUS) and endobronchial ultrasonography (eBUS) are increasingly being used to detect mediastinal involvement in bronchogenic and esophageal carcinoma and guiding diagnostic aspiration of lymph nodes that would otherwise not be possible by conventional methods.

Radionuclide Imaging

Positron emission tomography (PET) with or without CT has almost become a prerequisite in the preoperative evaluation of bronchogenic carcinoma for assessing respectability. Radioactive iodine scans are useful in detecting mediastinal extension of suspected thyroid neoplasms. Technetium-99m (Tc-99m) sestamibi can be used to detect parathyroid tissue.

Pneumomediastinum

Free air in the mediastinum detected on a chest X-ray or chest computed tomography test is pneumomediastinum.[7] It is spontaneous when occurring without surgical or medical procedures, chest trauma or mechanical ventilation and in the absence of underlying lung disease. Secondary pneumomediastinum, though a rare entity, is far more common especially in recent times with mechanical ventilation patients. Both the entities vary distinctly in the pathophysiology, clinical presentations and are discussed separately. The key to understand the distribution of extraalveolar air lies in the recognition of the common facial planes that unite these areas. Anatomical continuity may lead to extensive subcutaneous emphysema over the head and neck area, interstitial emphysema, pneumoperitoneum or air may dissect the pleural layers/pericardium leading to associated pneumothorax/pneumopericardium. The source of air includes alveolar in spontaneous and pneumomediastinum associated with mechanical ventilation. Other areas of origin include head and neck where it could be secondary to infection by gas producing organisms or dental procedures requiring use of compressed gas at high pressures. Upper respiratory tract, tracheobronchial tree and extrathoracic gas are the source in trauma patients; uncommon sources include pneumoperitoneum and pneumoretroperitoneum in postsurgical patients.

Spontaneous Pneumomediastinum (SPM)

This entity was first recognized in 1939 by Hamman with the demonstration of crepitations synchronous with heart which is classically described as "Hamman's crunch". Idiopathic SPM is rare with a reported incidence of 0.001 to 0.01% among all adult inpatients.[7] Most cases are young males; the age is distributed roughly from 18–25 years old and males account for 73.1%.[8] No relation is reported with either smoking or other environmental factors. Pressure differences across the alveolar membrane resulting from rapid increments of airway pressure cause terminal alveolar rupture. Most commonly, this results from straining against a closed glottis, as during vomiting, coughing or exercising. Other factors such as direct toxic effects of heat induced by inhalation of illegal drugs and the thinner alveolar wall due to malnutrition may result in the rupture.[9] This rupture occurs without pleural dissection, which causes air to enter the lung interstitium and then migrate towards the mediastinum, occasionally the pericardium and the retropharyngeal and the retroperitoneal space, along the bronchovascular bundle by the pressure gradient between the peripheral and the hilum of the lung, the so-called Macklin effect.[10]

Most common presenting symptoms are chest pain and dyspnea. The pain typically radiates to the neck or back and is aggravated by bending forward, swallowing or deep inspiration. Other symptoms include cough and dysphonia. Differential diagnosis in any young person presenting with acute chest symptoms should include SPM. Severity of symptoms is usually moderate and patients tend to present within 24 hours of onset of symptoms. History regarding trigger events may help in clinching the diagnosis but no trigger is identified in up to 40 % of cases. Subcutaneous emphysema detected in up to 62% of the reported cases is the most common physical finding and is usually restricted to the head and neck region. Hamman's crunch is reported in 30% of cases, careful auscultation with placement in left lateral position improves the chances.[11]

Radiological Findings

Common findings in chest radiograph PA view are air streaks in the superior mediastinum (sometimes they reach to the neck), the prominent silhouette of the heart (especially on the left) and subcutaneous emphysema of the shoulder and neck. All the findings may not be identified in a given patient. The double bronchial wall sign (bronchial wall sandwiched between inner and outer air) and the continuous diaphragm sign (the diaphragm of both sides appearing connected by leaked air between the inferior surface of heart and diaphragm) are uncommon but characteristic signs when present.[8] Lateral views are more sensitive in detecting air and must be used when the clinical suspicion is high and frontal radiographs are unrevealing. One must resort to computerized tomography when strong clinical suspicion is present with normal chest radiograph. CT is also informative regarding additional lung disease and in complicated pneumomediastium like Boerhaave syndrome.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis includes pneumothorax, pulmonary thromboembolism, pericarditis and acute coronary syndrome. Since all differentials are more common in emergency setting, the risk of them being missed while a patient is being evaluated for SPM is slim. Whilst SPM is detected, one should be careful to rule out Boerhaave syndrome as it carries high mortality unlike SPM.

Treatment and Clinical Course

Symptoms tend to subside in 24–48 hours with complete radiological resolution. Symptomatic therapy with analgesics is all that is required in most of the cases. Antibiotics may be considered in the presence of signs of inflammation like fever after ruling out other differentials. Subcutaneous emphysema is drained using tunneled intravenous catheter if extensive and an associated pneumothorax is managed by chest tube drainage. Recovery is total with recurrence uncommon (1.2%) unlike in spontaneous pneumothorax.[8]

Pneumomediastinum in Mechanically Ventilated Patients

Mechanically ventilated patients who are subjected to high tidal volumes, high peak inspiratory pressures, high positive end expiratory pressures (PEEP) and are fighting the ventilator are at high risk for developing pneumomediastinum.[12] Air trapping (auto PEEP) due to high frequency or underlying obstructive lung disease may also lead to increase in peak inspiratory pressures. Unlike SPM, pneumomediastinum in mechanically ventilated patients can be life threatening due to continuous positive pressure increasing the likelihood of associated tension pneumothorax. This may be detected incidentally on chest radiograph; but once detected, serial screening with chest radiograph is required to detect pneumothorax. If a pneumothorax occurs; chest tube drainage is indicated regardless of the size, if the patient continues to require positive pressure ventilation. In the presence of only pneumomediastinum, a step to curb increase in peak inspiratory pressures is taken, if the patient cannot be immediately weaned off the ventilator. Patient-triggered, pressure limited ventilation (e.g. inspiratory pressure support) or low-rate intermittent mandatory ventilation would probably be preferable to mandatory volume-limited ventilation if clinically feasible.[13] Prophylactic bilateral chest tube insertion is not recommended in the absence of sudden deterioration.

MEDIASTINITIS

Inflammation of the mediastinal structures is defined as mediastinitis. Based on the duration and severity of symptoms it may be broadly classified to acute and chronic. Clinical presentation is dramatic and is often life threatening in acute mediastinitis whereas chronic inflammation tends to present as mediastinal mass.

Acute Mediastinitis

Infection is the most common cause of acute mediastinitis but predominant inflammation could also occur with secondary infection as in esophageal rupture. Based on etiology, specific compartments may be more commonly involved but with time inflammation spreads to all. With the advent of invasive endoscopic therapeutic procedures esophageal perforation is the most common cause of acute mediastinitis. Other common causes include infection following sternotomy, descending necrotizing mediastinitis following neck infections, infection from tracheobronchial tree and rarely direct involvement as in anthrax mediastinitis.

Patients are usually gravely ill, high index of suspicion is the key especially in post procedure patients as in esophageal manipulation or cardiac surgery as they tend to deteriorate rapidly developing multiorgan dysfunction within few hours. Computerized tomography of the chest with contrast enhancement is the investigation of choice in these patients. Treatment of these patients require appropriate antibiotics and surgical debridement (Table 121.2).

Chronic Mediastinitis

The active end of the spectrum encompasses granulomatous mediastinitis and at the other end mediastinal fibrosis represents the sequelae. The former tends to be asymptomatic whereas the latter presents as mass with symptomatic profile depending on the part of mediastinum which is involved. Histoplasmosis and tuberculosis are fine examples which demonstrate the etiology of chronic mediastinitis. Both being as infection in the lungs with mediastinal adenitis secondary to regional drainage. There can be associated perinodal inflammation in a subset of individuals with a residual breakdown of conglomerate of lymph nodes akin to matting seen in the periphery. This mass gets covered by a fibrous capsule and tends to calcify as it is usually seen in chest radiograph as a sequelae. In some individuals, the fibrous capsule tends to increase in thickness with compression and invasion of adjacent organs. The reason for its occurrence in certain individuals and not in others is unclear. Goodwin and associates postulated that prolonged gradual seepage of some soluble antigen or other substance from the involved lymph nodes, at least in patients with histoplasmosis, causes fibrosis.[14] In some

TABLE 121.2: Management of acute mediastinitis

Etiology	*Investigation*	*Antibiotics*	*Surgical procedure*
Descending necrotizing mediastinitis	Contrast enhanced CT of neck and chest	Anaerobic and gram negative organisms	Surgical drainage
Esophageal manipulation	Contrast esophagogram, contrast enhanced CT of chest	Gram-negative organisms, methicillin resistant *Staph.* aureus (MRSA)	Debridement and closure of perforation
Boerhaave syndrome	Contrast esophagogram, contrast enhanced CT of chest	Gram-negative organisms	Debridement and closure of perforation
Post sternotomy	Contrast enhanced CT of chest	Pseudomonas and MRSA	Extensive sternal and mediastinal debridement
Tracheobronchial perforation	contrast enhanced CT of chest	Gram-negative organisms, MRSA	Stenting/open surgical repair
Anthrax mediastinitis	Chest radiograph, contrast enhanced CT	Ciprofloxacin or doxicycline + clindamycin	

patients with concomitant retroperitoneal fibrosis, autoimmune phenomena might be responsible.

Clinical Manifestations

Predominant symptoms are manifestations of mass effect on the adjacent organs. Cardinal symptoms include cough, chest pain, hemoptysis and dyspnea. Trachea or any of the major bronchi can be involved but compression or erosion of the right middle lobe is most common and may present as right middle lobe syndrome. Right paratracheal region involvement may lead to compression of superior vena cava, leading to superior vena cava (SVC) syndrome. Though malignancy accounts for up to 95% of SVC syndromes encountered in clinical practice, fibrosing mediastinitis is the most common nonmalignant cause. Extrinsic esophageal compression presents as dysphagea and perforation as hematemesis or tracheoesophageal fistula. Recurrent laryngeal nerve compression leads to hoarseness of voice. Pulmonary vascular involvement can lead to pulmonary hypertension and cor pulmonale.

Management

Chest radiology reveals mediastinal enlargement, definite diagnosis requires mediastinal sampling by exploratory laparotomy to exclude malignancy. During the same, debulking of the mediastinum should be attempted while being careful to avoid injury to surrounding structures. Antitubercular or antifungal can be given if specific infections are identified. Anti-inflammatory agents like steroids have been used with equivocal results but may be considered in an individual patient. Mechanical compression can be relieved by endovascular, esophageal or endobronchial stenting where appropriate.

TUMORS AND CYSTS OF MEDIASTINUM

Mediastinal mass may be congenital or acquired in origin, the contents of the mediastinal compartments serve as points of origin. Hence localization of the mass in mediastinum gives a clue towards etiology but can be confirmed only by tissue sampling. The contents of the respective compartments have been summarized in Table 121.1. Anterior mediastinal mass most commonly arises from thymus, lymph nodes, thyroid or primitive germ cells. The middle compartment which mostly comprises of tracheobronchial tree, heart and esophagus is the site for duplication cysts. Posterior mediastinum abuts the vertebral body, enclosing the sympathetic trunk and vagal nerve; mass arising from this region is likely to be of neural origin. Location of the mass, age of presentation and presence of symptoms are the three major determinants of whether the mass is benign or malignant in etiology. Although majority of mediastinal masses are benign (2/3rd), anterior mediastinal (59%) and symptomatic lesions (85%) are more likely to be malignant.[1] Symptoms are broadly classified into local and systemic. The local symptoms are secondary to the mass effect and compromise of surrounding structures. Common symptoms include cough (60%); chest pain (30%); and dyspnea (16%). Systemic manifestations are due to the release of excess hormones, antibodies or cytokines and are typically seen in malignant neoplasm as a part of paraneoplastic syndrome. These include cachexia, anorexia, fever, neurologic and endocrine manifestations.

Mediastinal imaging has been discussed in detail at the beginning of the chapter. Recapitulating the salient points, the initial workup of a suspected mediastinal mass involves obtaining PA and lateral chest radiographs. This can provide information pertaining to the size, anatomic location, density, and composition of the mass. CT scanning is used to further characterize mediastinal masses and their relationship to surrounding structures as well as to identify cystic, vascular, and soft-tissue structures.[15]

The role of MRI is primarily in ruling out or evaluating a neurogenic tumor. Magnetic resonance imaging is also valuable to evaluate the extent of vascular invasion or cardiac involvement.[16]

Mediastinal Sampling

Tissue diagnosis of mediastinal lesions can be performed using surgical techniques such as thoracoscopy, cervical mediastinoscopy, extended cervical mediastinoscopy and anterior mediastinostomy and needle biopsy techniques, such as image-guided percutaneous needle biopsy, transbronchial needle biopsy including endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-FNA) and transesophageal endoscopic ultrasound guided fine-needle aspiration biopsy (EUS-FNA).[17] Minimally invasive transcutaneous or transpulmonary image guided fine-needle aspiration or biopsy is preferred over open surgical techniques as the diagnostic yield is comparable with a dramatic reduction in complication rates. Choice of the procedure is also dictated by its local availability, institutional and physician preference, patient's condition and location as well as size of the lesion.

Transbronchial needle aspiration (TBNA) through a flexible bronchoscope is the time tested method for sampling enlarged subcarinal and hilar lymph nodes. This is limited by the absence of real time imaging and hence can be used only in the presence of lymph nodes of at least 1.5–2 cm in diameter. The reported sensitivity when used to stage non small cell carcinoma is 25–81%.[18] Endobronchial ultrasound-guided transbronchial needle aspiration, has been documented to have high diagnostic value, with sensitivity of more than 90% in the staging of non-small cell lung cancer.[19] Transesophageal endoscopic ultrasound (EUS) guided needle biopsy allows access to the lower paratracheal, subcarinal, aortopulmonary and paraesophageal regions. The reported sensitivity of EUS-guided biopsy in the mediastinum is 82 to 96%.[18] However, anterior lymph nodes, including those in the pretracheal and high right paratracheal regions, are not accessible because of the interposition of the air-filled trachea.

Before the advent of minimally invasive techniques, all patients of bronchogenic carcinoma planned for resection were subjected to cervical mediastinoscopy. Even now this is the procedure of choice when multiple lymph node stations need to be sampled for accurate staging. It allows direct visualization and sampling of pretracheal, paratracheal and anterior subcarinal lymph nodes and is reported to yield a diagnosis in 83 to 89% of patients with lung cancer.[20,21] It is done under general anesthesia with 1 to 3% risk of major complications and aortopulmonary, retrotracheal, posterior subcarinal and inferior mediastinal lymph nodes are inaccessible. Extended cervical mediastinoscopy, anterior mediastinotomy and thoracoscopy are alternative surgical techniques, which can be used to assess mediastinal regions not accessible by standard mediastinoscopy.

Percutaneous transthoracic needle biopsy using image guidance under local anesthesia and conscious sedation allows access to virtually all mediastinal regions including those that are inaccessible by mediastinoscopy, transbronchial biopsy and EUS-guided biopsy. The accuracy of transthoracic biopsy for the diagnosis of mediastinal lesions ranges from 75 to 90%.[20,21] A major limitation of this technique is the risk of pneumothorax, reported to occur in anywhere from 10–60% of cases. If encountered, it can be managed by percutaneous single time aspiration or by chest tube drainage.

ANTERIOR MEDIASTINAL MASS

Thymic tumors and cysts constitute most of anterior mediastinal masses (Table 121.3).

Thymoma

Thymomas account for 20% of anterior mediastinal neoplasms in adults.[22] Systemic manifestations such as myasthenia gravis (30–50%), hypogammaglobulinemia (10%) and pure red cell aplasia (PRCA) may be the primary presentation and the mediastinal mass may be detected incidentally during evaluation. Thymomas have a wide spectrum of histologic diversity and are classified based on cell type predominance as lymphocytic, epithelial or spindle cell variants. There is a strong association between histologic subtype and invasiveness as well as

TABLE 121.3: Tumors and cysts of thymus

Tumor	*Incidence*	*Association*	*Poor prognostic markers*	*Treatment*
Thymoma	20% of anterior mediastinal mass	Myasthenia gravis, hypo-gammaglobulinemia, PRCA	Metastasis,size >10 cm, tracheal/vascular compression, age >30 years,epithelial or mixed histology, PRCA	Surgical resection, palliative chemotherapy and radiation
Thymic carcinoma	Rare	—	Tumor margin infiltration, absence of a lobular growth pattern,high-grade atypia and necrosis, >10 mitoses per high power field	Surgical resection, palliative chemotherapy and radiation
Thymic Carcinoid	8% of MEN 1 syndrome	Cushing's and multiple endocrine neoplasia (MEN) syndrome	Regional and distant metastasis	Surgical resection, chemo-therapy and radiation not effective
Thymolipoma	Rare	-	Benign	Surgical resection
Thymic cysts	Rare	Inflammation, Hodgkin's disease or other congenital abnormality	Acquired or congenital, benign	Surgical resection

prognosis. Thymomas are usually solid tumors but may have cystic areas due to degeneration, necrosis or hemorrhage. Thirty-four percent of thymomas invade through their own capsules, extending into surrounding structures.[23,24] There can be transdiaphragmatic or pleural extension but distal lymphatic or hematogenous spread is rare. As classification system proposed by the World Health Organization is based on cytologic differences, which may be helpful in determining treatment regimens and predicting survival.[25]

The Masaoka clinical staging system is based on the degree of invasion of the tumor through the capsule into the surrounding structures, which has important implications for prognosis.[26] In the study by Okumura et al.[27], the Masaoka staging system was shown to be useful as an independent predictor of survival in patients with thymoma. Diagnosis is easily established by percutaneous image guided fine needle aspiration, but capsular invasion can only be made out on histopathologic examination of excision biopsy. Surgical excision is the standard of care for both invasive and non-invasive thymomas as it is the only potentially curative option. Adjunctive chemotherapy and radiation is used for locally invasive or metastatic disease, or inoperable tumors.

Mediastinal Germ Cell Tumors (GCTs)

Speculations regarding etiology have ranged from the opinion that these tumors are really of gonadal origin and represent spread from an occult or "burned out" primary tumor to the view that these tumors are of true extragonadal origin with separate clinical and biological behaviors. Primitive germ cells that fail to migrate completely during early embryonic development is the currently accepted theory regarding the origin of GCTs. They constitute about 15% of anterior mediastinal masses. GCTs are classified into the following three groups based on cell type: Benign teratomas; seminomas; and embryonal tumors/malignant teratomas/ nonseminomatous GCTs.

Teratomas

Teratomas are derived from at least two of the three primitive germs layers. They are subclassified into mature and immature (malignant) teratomas, based on the cell of origin. Mature teratomas are more common and are histologically well defined. Ectodermal tissues, which usually predominate, include skin, hair, sweat glands and tooth-like structures. Mesodermal tissues, such as fat, cartilage, bone and smooth muscle are less common, as are endodermal structures like respiratory and intestinal epithelium.[28] Malignant teratomas contain fetal or neuroendocrine tissue, have a favorable prognosis in children but can recur or metastasize.

Mature teratomas tend to be silent or may present with the cardinal mediastinal symptoms. Occasionally, the presentation may be dramatic with the expectoration of hair or sebum due endobronchial rupture of teratoma or rarely malignant transformation. Typical radiological picture is well-defined round or lobulated mass with up to 26% showing calcification due to presence of bone or teeth elements. Computed tomography or MRI may reveal sebaceous elements or fat, which may further support the diagnosis and help in assessing resectability. Complete surgical resection is the treatment of choice and adjuvant chemotherapy is indicated if resection is incomplete.

Medistinal Seminoma

Approximately 40% of mediastinal GCTs are seminoma, occurring most commonly in males between second and the fourth decade. Apart from the usual presenting features of mediastinal mass, gynecomastia and weight loss may occur as paraneoplastic manifestations. Beta human chorionic gonadotropin (β-HCG) is elevated in up to 10% of patients but an elevated alpha fetoprotein (AFP) suggests an alternate diagnosis. Radiographically, seminomas are bulky, lobulated, homogenous masses. Local invasion is rare, but metastasis to lymph nodes and bone does occur.[29] Computed tomography and gallium scanning is used to evaluate the extent of disease. Unlike other mediastinal tumors discussed till now, seminomas are highly radiosensitive. Management may involve only radiotherapy or chemotherapy and radiotherapy or a neoadjuvant chemotherapy followed by surgery. Five-year survival ranges between 54% with radiotherapy alone[30] to more than 90% with chemotherapy with or without radiation[31] among various studies.

Nonseminomatous GCTs

The nonseminomatous malignant germ cell tumors include embryonal cell carcinoma, endodermal sinus tumor, choriocarcinoma or mixed germ cell tumors composed of multiple histologic features. These are malignant and typically cause symptoms in young adult men. Unlike seminomas, lactate dehydrogenase and serologic markers such as AFP and β-HCG are frequently positive. Another unique association is with hematologic malignancies with up to 20% of the patients having Klinefelter's syndrome.[29] Radiologically, these are large, irregular, anterior mediastinal masses, often with extensive, central, irregular and heterogeneous areas of low attenuation due to necrosis, hemorrhage and/or cyst formation. Invasion of adjacent structures with associated pleural and pericardial effusions are common. Tumor may protrude through the chest wall and distal metastasis is not uncommon. Chemotherapy with bleomycin, etoposide and cisplatin is the current standard of care for patients with nonseminomatous malignant GCTs. Complete response is rare, with most patients requiring resection of residual tumor. As compared to seminomas, nonseminomatous GCTs have a poor long-term survival with only 46% alive at five years in contrast to 86%.[32]

Mediastinal Goiter

Clinically mediastinal extension of goiter is detected by inability to identify the lower border of thyroid during examination. Incidence is in the range of 1 to 15% among patients undergoing thyroidectomy. Most patients are euthyroid; Goiter appears as lobulated, encapsulated and heterogenous tumors with classic cervicomediastinal continuity seen on CT. There will be avid uptake of radioiodine if there is functional thyroid tissue. Due to retrosternal position, diagnostic sampling is difficult and exploratory laparotomy with complete surgical excision is recommended as malignancy develops in a significant number.

Mediastinal Lymphomas

Mediastinal involvement as a part of systemic disease is a common manifestation of lymphomas and figures among the top differentials while evaluating mediastinal lymphadenopathy. Primary mediastinal lymphoma is relatively rare entity accounting for only around 10% of all mediastinal lymphomas. Nodular sclerosing type of Hodgkin's lymphoma, large B-cell lymphoma and lymphoblastic lymphoma are the three most common lymphomas with mediastinal involvement.[29] Presentations are similar to other mediastinal masses with constitutional symptoms (B symptoms) predominating at times especially in Hodgkin's lymphoma. They can present as mediastinal emergencies with superior vena cava syndrome or pericardial tamponade leaving little time for establishing diagnosis. Diagnosis is achieved by sampling peripheral or mediastinal lymph nodes whichever is less invasive. Ann Arbor staging system is based on the number of lymph node regions and or other organ systems involved by the disease process. The treatment of mediastinal lymphomas is no different from lymphomas elsewhere and it involves primarily appropriate chemotherapy. Adjuvant radiotherapy may be justified in stage I or II a disease or in the presence of superior vena cava syndrome. Relapsed disease is usually treated with high dose chemotherapy followed by bone marrow transplantation.

TUMORS OF THE MIDDLE MEDIASTINUM

Mediastinal Cysts

These are congenital anomalies resulting from defects during embryonic development. They occur most commonly in the middle mediastinum but neural derived cysts are found in the posterior mediastinum. Their presentation can be insidious due to compression of adjacent structures or acute due to infection or rupture. They comprise 12 to 20% of mediastinal masses and the most common type of mediastinal cyst are foregut cysts, with enterogenous cysts (50 to 70%) and bronchogenic cysts (7 to 15%) being the major subtypes.[29]

Bronchogenic Cyst

Approximately 40% of the bronchogenic cysts are symptomatic with cough, dyspnea or chest pain whereas the rest are detected during routine chest radiographs.[33] The lung bud develops caudally from the laryngotracheal tube, beginning in the fourth week of gestation. By the fifth week, the single bud has divided into right and left main bronchi, which grow into the surrounding splanchnic mesenchyme and are destined to become bronchial cartilage and smooth muscle as well as visceral pleura. Dichotomous branching of the primitive bronchi continues until about the 24th week, when the terminal bronchioles begin to give rise to primitive alveoli. Throughout this period of embryogenesis, abnormal bronchi and bronchioles may form larger saccular structures, which are clinically recognized as bronchogenic cysts and are lined with ciliated, pseudostratified, columnar epithelium and contain bronchial glands and cartilaginous plates. Anomalies that occur early are contained within the mediastinum and are mostly commonly seen abutting the trachea, carina or hila. Less frequently, errors occurring late in embryogenesis may result in intraparenchymal bronchogenic cysts. They are seen as well-defined rounded masses on chest radiographs and on CT have similar Hounsfield unit as water. Air fluid level signifies either bronchial communication or secondary infection. Diagnosis is confirmed by imaged guided or endobronchial needle aspiration. Symptomatic cysts are managed by either surgical resection or therapeutic aspiration with or without instillation of sclerosing agent (ethanol or bleomycin) but controversy exist regarding the management of asymptomatic cysts. Subjecting such patients to a major surgery must be weighed against potential long-term complications including malignancy.

Enterogenous Cyst

Enterogenous cysts arise from the dorsal foregut and are lined by squamous or enteric (alimentary) epithelium and may contain gastric or pancreatic tissue. It is also known as esophageal duplication cyst and represents the failure of esophagus to separate from the respiratory tract, a process which normally occurs around the fifth week during embryogenesis. Communication to the alimentary tract is rare and is usually spherical with cystic consistency. Twelve percent may have associated other malformations of the gastrointestinal tract. Majority of the patients present in early childhood and due to presence of gastric or pancreatic tissue, there is a potential for hemorrhage or rupture. There is predilection for the right side and symptomatic dyspnea is rare. In asymptomatic patients, the most common clue leading to this diagnosis is the coexistence of other gastrointestinal duplications. Radiological manifestations are similar to bronchogenic cysts but these have slightly thicker wall and are nearer to esophagus. Barium meal may show indentation along the posterior wall and a technetium pertechnetate nuclear scan may suggest the presence of ectopic gastric mucosa within the chest. The potential for rupture mandates surgical resection of all enterogenous cysts after confirming diagnosis. The presence of gastric lining mucosa also predisposes these patients for the development of adenocarcinoma and hence the need for long-term follow-up post surgery.

Pericardial Cysts

Unlike other cystic lesions of the middle mediastinum, pericardial cysts are often detected in the fourth to fifth decade. Therefore the case for at least some of them being acquired is strong but majority of them seem to be form from the persistence of parietal recess during embryogenesis. Most are asymptomatic but can present with hemodynamic compromise secondary to cardiac compression or arrhythmia. Their estimated incidence is 1 in 1,00,000.[33] The most common presenting site is the cardiophrenic angle on the right side and can be mistaken for foramen of morgagni hernia or thickened pericardial fat. They are also called “spring water cysts” because of their characteristic radiologic picture showing low density clear serous fluid content. Pericardial cysts have no malignant potential and can therefore be followed up once diagnosis is established. Symptomatic cysts are resected by either an open or endoscopic approach.

Lymphangiomas

Lymphangiomas classically present as cervical swelling and are identified clinically by the presence of fluctuation and transluminescence due to presence of clear fluid. In up to 10% of patients there can be a mediastinal extension with associated chylothorax and hemangioma. These are congenital malformation of the lymphatics leading to saccular dilatation and cyst formation. Cervical lymphangiomas typically present in early childhood but isolated mediastinal lesions may present during adult life with symptoms of mediastinal compression. Radiographically, these lesions appear cystic and can be confused with pericardial cysts, although lymphangiomas are more likely to have a loculated appearance.[34] The use of lymphangiographic contrast media combined with CT scanning can also differentiate these lesions. Complete surgical resection is the treatment of choice, however in cases complicated by adjuvant radiotherapy may be used.[35] Lymphangiomatosis (LAM), a type of cystic interstitial lung disease, seen almost exclusively in women may be an advanced form of lymphangioma of chest.

TUMORS OF THE POSTERIOR MEDIASTINUM

Neuroenteric Cysts

Enterogenous cysts that are in continuation or adjacent to vertebral anomalies are called neuroenteric cysts. Neurenteric cysts are very rare congenital anomalies. Result due to failure or incomplete separation of the notochord from the primitive foregut. Associated vertebral anomalies include butterfly vertebrae, hemivertebrae and anterior spina bifida. These cysts may present early in life often before the first year of life with triad of respiratory symptoms, mediastinal mass and vertebral anomaly. Evaluation should include imaging of the chest with CT and a complete spinal imaging using MRI spine. Treatment usually requires cooperation between neurosurgeon and cardiothoracic surgeon for spinal decompression, vertebral reconstruction and mediastinal resection. Given the complexity of the procedures, usually a staged approach is preferred and residual neurologic deficit may be present.

Neurogenic Tumors

Neurogenic tumors arise from various neural elements like peripheral nerve roots (neurofibroma, schwannoma, neurogenic sarcoma), from the sympathetic ganglia (ganglioneuroma, ganglioneuroblastoma and neuroblastoma), from aorticosympathetic paraganglia (paravertebral paraganglioma), or rarely from the intrathoracic spinal canal (e.g. meningocele or meningomyelocele).[36] They constitute about 20% of all mediastinal masses and roughly 95% of them lie in the posterior mediastinum. Nearly three fourth of them are benign and half are asymptomatic; however, they can occasionally cause compressive or neurologic symptoms.[37]

Nerve Sheath Tumors

They constitute about half to two-third of the neural tumors of the posterior mediastinum. These are benign and extremely slow growing tumors consisting of neurilemmoma or schwannomas and neurofibromas. The former are encapsulated, firm masses consisting of Schwann cells whereas the latter are soft, friable, nonencapsulated and associated with neurobifromatosis. They appear as sharply marginated spherical masses on radiographs with often signs of erosion of adjacent spine. The classic dumbbell appearance due to growth of tumor through the interevertebral foramina is seen in only 10% of the tumors. Complete surgical resection is the standard of care and adjuvant chemotherapy or radiotherapy may be considered if resection is incomplete. Paraparesis and Horner's syndrome are potential complications of surgery.

Malignant nerve sheath tumors are the spindle sarcomas of posterior mediastinum, and include malignant neurofibromas, malignant schwannomas and neurogenic fibrosarcomas. They are generally symptomatic, with pain and nerve deficits being the predominant symptoms. Complete surgical resection with or without adjuvant chemotherapy or radiotherapy is the treatment of choice.

TUMORS OF AUTONOMIC NERVOUS SYSTEM

These tumors arise from neuronal cells rather than from the nerve sheath. They are either benign or encapsulated like the ganglioneuroma or can be fast growing, malignant and nonencapsulated like the neuroblastoma. They arise either from the adrenals or from the sympathetic ganglia of the posterior mediastinum. Surgery is the treatment of choice for benign tumors and localized malignant tumors can be excised completely. If the resection is incomplete, treatment regimen includes postoperative chemotherapy and radiotherapy.

SUPERIOR VENA CAVA SYNDROME (SVCS)

No review of mediastinum would be complete without an overview of this dramatic syndrome which, once seen in clinical practice remains etched in the memory of any clinician. SVCS is a common complication of lung cancer and non-Hodgkin's lymphoma (NHL). Two to four percent of lung cancer and NHL develop SVCS and together, they constitute about 90% of the cases of SVCS seen in modern practice.[38] Benign causes constitute around 5–10% of the cases and are usually due smoldering infections secondary to tuberculosis or fungus, thrombosis due to iatrogenic procedures like central venous or Swan-Ganz catheter or pacemaker leads.

Severity of the presenting complaints depends on the site of occlusion (site distal to azygos vein is more symptomatic than proximal) and the rate of onset of occlusion. If the occlusion is insidious onset then the collaterals effectively decompress the system and hence the symptoms are minimal. Collaterals include azygos, intercostal, mediastinal, paravertebral, hemiazygos, thoracoepigastric, internal mammary, thoracoacromioclavicular and anterior chest wall veins. Collaterals often take several weeks to dilate and accommodate the diverted blood from SVC. Clinically, the site of obstruction is at the level of SVC is identified by the above downward direction of flow in the collaterals both above and below the umbilicus. Patients present with symptoms of dyspnea, orthopnea, chest pain, hemoptysis, swelling of neck, upper limbs and face, dilated veins in the upper chest wall, headaches, confusion and rarely seizures due raised intra cranial tension. Radiologic examination with a contrast enhanced CT will identify the mass lesion and the presence of collaterals on CT is highly sensitive and specific for presence of SVCS.[39] If suspected, CT angiography can detect the site and extent of the thrombus.

Evaluation of these patients should be quick as they can deteriorate rapidly. Careful general examination should be carried out to look for peripheral lymphadenopathy as the access to such tissue is easier. Patients often have pleural effusions but these are often secondary to venous hypertension and are unlikely to yield the diagnosis but should be examined nonetheless. Patient's orthpnea may preclude image guided sampling of the mediastinal mass as these procedures require the patient to lie supine. Under such circumstances, endoscopic stenting of the SVC is the treatment of choice in relieving the symptoms when diagnosis is not established. Stenting provides near total relief of symptoms within 24–72 hours and subsequently the patient is able to undergo mediastinal sampling.[40] Once diagnosis is established, patients may undergo chemotherapy in cases of lung cancer and lymphoma or radiotherapy in cases small cell carcinoma of lung.

All patients should receive supportive care with oxygen supplementation, head end elevation, restriction of fluids and diuretics. Use of steroids before tissue diagnosis is established should be discouraged as it may lead to architectural distortion making subsequent biopsies difficult to interpret. Median life expectancy in patients with SVCS is approximately six months with a range of 1.5–9.5 months; however, estimates vary widely and are dependent on the underlying malignant condition.

Diseases of Thoracic Cage

Balamugesh T

INTRODUCTION

The chest wall comprises of the rib cage, rib cage muscles and the diaphragm. Disorders involving the chest wall may ultimately affect ventilation and eventually lead to respiratory failure. The important nonmuscular conditions of the chest wall are briefly discussed.

KYPHOSCOLIOSIS

Kyphoscoliosis is a group of conditions in which the patients have scoliosis (lateral curvature of the spine) and kyphosis (backward curvature of spine) (Fig. 122.1). Based on the etiology, the curvature abnormalities can be considered in three groups:

1. *Congenital:* Neurofibromatosis, Friedreich's ataxia, muscular dystrophy, Ehlers-Danlos syndrome, Marfan's syndrome, etc.
2. Paralytic: Poliomyelitis, muscular dystrophy, cerebral palsy, Friedreich's ataxia
3. Idiopathic

Kyphoscoliosis is idiopathic in approximately 80% cases, with a female predominance (4:1).

The severity of kyphoscoliosis is determined radiologically using the Cobb angle. Two lines are drawn parallel to the upper border of the highest and the lower border of the lowest vertebral body of the curvature as seen on an anteroposterior radiograph of the spine respectively. The angle made by two lines drawn perpendicular to these lines at the intersection point is measured (Fig. 122.2). An angle of more than 10 degrees defines scoliosis, and of more than 100 degrees is indicative of severe scoliosis with a higher risk of progression to respiratory failure.

Pulmonary Function Tests

Predicted values for lung function in patients with kyphoscoliosis should be calculated on the basis of arm span measurements because of reduction in height due to spinal deformity.[1] Restrictive ventilatory pattern is seen in patients with severe kyphoscoliosis with

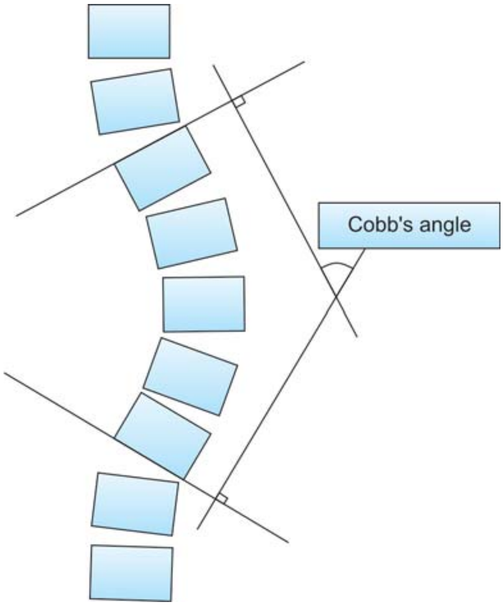

Fig. 122.2: Cobb's angle

reduction in vital capacity (VC) and total lung capacity (TLC).[2,3]This is due to reduction in chest wall compliance. In order to reduce the work of breathing, the patients adopt a pattern of rapid shallow breathing. This in turn leads to reduction in lung compliance due to micro-atelectasis and increases the dead space ventilation. Those with paralytic kyphoscoliosis have a pronounced reduction in inspiratory muscle strength and a greater reduction in VC. Even in those with Cobb's angle greater than 50°, there is significant reduction in inspiratory and expiratory muscle strength attributed to altered chest wall geometry and resultant mechanical disadvantage of the respiratory muscles.

Some patients have airway obstruction in addition to lung restriction; this is due to the presence of bronchial torsion and compression of the central airways.[4] The increase in oxygen cost of breathing may place these patients at a high risk of respiratory muscle fatigue. The residual volume (RV) is normal with an increase in RV/TLC ratio. Diffusing capacity for carbon monoxide (DLCO) is reduced in proportion to the reduction in lung volumes, giving normal values for transfer factor (KCO).[5] In some patients, DLCO is disproportionately reduced and is attributed to failure of alveolar development and pulmonary hypertension.[6] The maximum oxygen consumption during exercise is reduced. The neural drive for breathing as measured by mouth occlusion pressure at 100ms (P 0.1) is normal or increased. But the ventilatory response to carbon-dioxide (CO_2) is decreased due to the reduced mobility of the stiffened chest wall.[5]

Sleep Disordered Breathing

The most common abnormality in patients with kyphoscoliosis during sleep is hypoventilation. In awake state, the intercostal and accessory muscles are recruited to assist the diaphragm in displacing the stiff chest wall. When sleeping, these patients may hypoventilate due to hypotonia of the intercostal and accessory muscles and decreased neural drive to diaphragm.[7] Since the chest wall movement is compromised, any degree of diaphragmatic dysfunction can aggravate hypoventilation during sleep. Untreated nocturnal desaturation can further worsen the respiratory muscle function leading to respiratory failure and cor pulmonale. The prevalence of obstructive sleep apnea is the same as in the general population, but if present, can further worsen the nocturnal hypoventilation.[8]

Prognosis

Prognosis is worse in those with a greater Cobb's angle and curvature at a higher level in the spine. In congenital and paralytic kyphoscoliosis, there can be progressive worsening skeletal deformity leading to respiratory failure. Individuals with idiopathic kyphoscoliosis have a more benign course. Once cor pulmonale develops, there is a rapid downhill course unless the treatment is started. Death usually occurs as a result of respiratory failure or cardiac diseases and the risks are high in juvenile and post polio scoliosis patients.[9] Pregnancy is poorly tolerated if the VC is less than 1 liter.

Medical Management

General measures include immunization against pneumococcal and influenza infections, prompt treatment of respiratory infections, smoking cessation, avoidance of sedatives, maintenance of ideal body weight and prevention of physical deconditioning by exercise. Supplemental oxygen may be required during activity or exercise.

Specific treatment of nocturnal hypoventilation whenever indicated, is provided by non-invasive positive pressure ventilation using a nasal or full-face mask (Table 122.1). Volume-preset and pressure-preset ventilators have equivalent physiological benefits.

The benefits of noninvasive nocturnal ventilation in patients with kyphoscoliosis include the improvements in quality of life, gas exchange, sleep architecture; and a reduction in pulmonary artery pressure.[11,12,13] Long-term noninvasive ventilation also reduces the number of hospitalizations due to respiratory failure. There are no remarkable changes in VC and respiratory muscle strength. The improvement in respiratory failure is due

TABLE 122.1: Indication for NIV[10]

Symptoms (e.g. fatigue, morning headaches, dyspnea)
OR
Signs of cor pulmonale
AND one of the following:

1. Daytime arterial $PCO_2 \geq 45$ mm Hg
2. Nocturnal oxygen saturation ≤ 88% for five consecutive minutes
3. Progressive neuromuscular disease with maximal inspiratory pressure (Pimax) <60 cm H_2O or FVC <50% of predicted

to increased ventilatory response to CO_2, prevention of respiratory muscle fatigue and reversal of microatelectasis. Negative pressure ventilation by cuirass, body wrap ventilators, or tank ventilators can aggravate upper airway obstruction during sleep and is usually not recommended.

Surgery for Kyphoscoliosis

Surgery plays an important role in those with kyphoscoliosis secondary to neurological disorders among children and adolescents.[14] Operative treatment traditionally consists of spinal fusion and/or insertion of Harrington rods, which may result in short term improvement of lung function. However, surgery can sometimes result in chronic back pain or further spinal deformities. Initial results of further refinements in surgical techniques are promising.[15]

Thoracoplasty

Thoracoplasty is a surgical technique that was used to collapse the lungs affected by tuberculosis, prior to the advent of antitubercular drugs (Fig. 122.3). It consists of various combinations of rib removal, artificial pneumothorax, phrenic nerve resection and compression of lung by insertion of foreign material. The patients who undergo thoracoplasty subsequently develop restrictive lung disease and chronic respiratory failure, as their age advances.

The severity of dysfunction is related to the number of ribs removed, presence of fibrothorax, degree of fibrosis of the underlying lung, phrenic nerve damage and the degree of scoliosis. There are significant associations between the development of cardiorespiratory or respiratory failure and factors such as the preoperative contralateral artificial pneumothorax, older age at operation, the presence of cavities before operation, and male sex.[16] Currently, thoracoplasty is used in rare situations such as post pneumonectomy complications, persistent tubercular bronchopleural fistula and sputum positive drug resistant tuberculosis.[17]

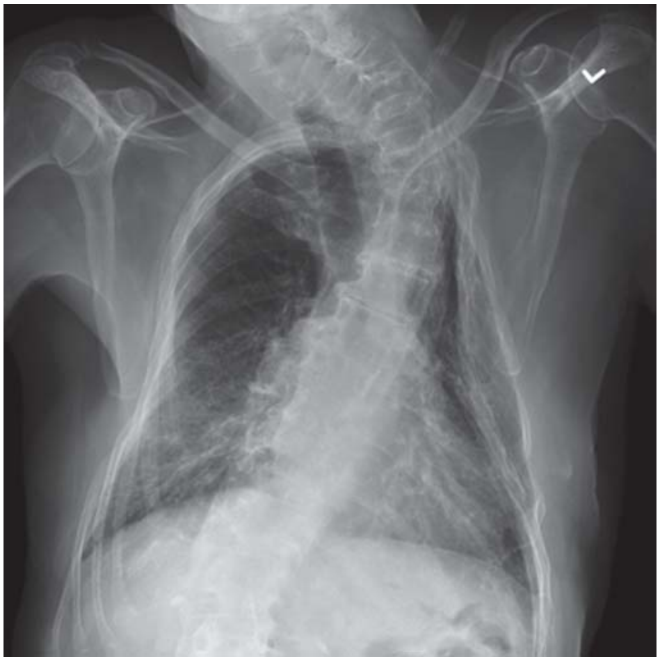

Fig. 122.3: Thoracoplasy (*Courtesy:* Dr. Frank Gaillard, www.radiopedia.org, used with permission)

In a series of 139 patients who underwent thoracoplasty in India, the indications for surgery were: Tubercular empyema (84 patients), pyogenic empyema (33 patients), postoperative empyema with bronchopleural fistula (8 patients), drug resistant pulmonary tuberculosis (2 patients) and recurrent hemoptysis (2 patients).[18] Successful outcome, i.e. the control of sepsis, closure of bronchopleural fistula, sputum conversion and control of hemoptysis, was achieved in the majority of patients. There were four deaths in the entire series. Thoracoplasty is therefore, still relevant in the developing countries where pulmonary tuberculosis continues to pose a challenging and persisting problem. In a recent series of 37 patients who underwent thoracoplasty and intrathoracic muscle transposition, the commonest indication was post pneumonectomy/lobectomy empyema.[19] Treatment of respiratory failure in post-thoracoplasty patients is the same as for those with kyphoscoliosis.[19]

PECTUS EXCAVATUM

Pectus excavatum, also known as "funnel chest", is characterized by excessive depression of sternum. It is the most common chest deformity seen by pediatricians. It is present in 0.4% of school children, more common among boys than girls.[20] The etiology is not clear, but a defect in the connective tissue surrounding the sternum and imbalance of forces counteracting the inward pull

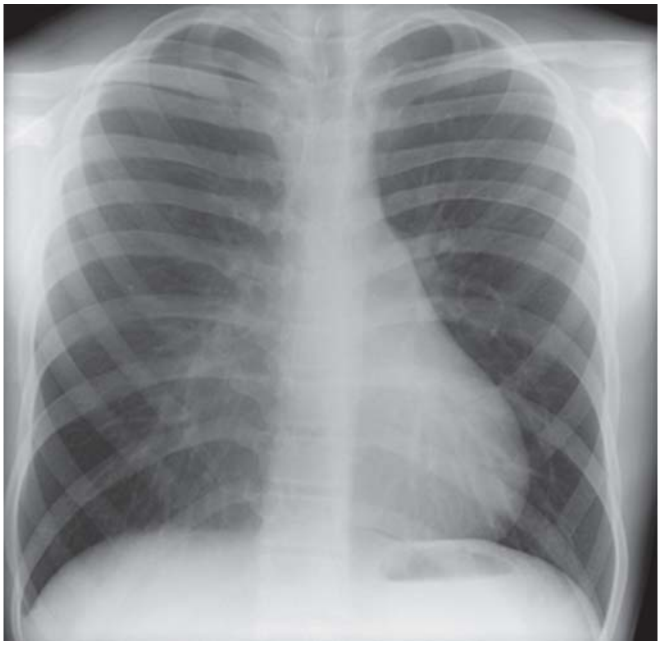

Fig. 122.4: Pectus excavatum: Chest radiograph PA view – Right paracardiac opacity due to parasternal soft tissue, could be mistaken for middle lobe infiltrate. (Image courtesy: Dr. Frank Gaillard, www.radiopedia.org, used with permission)

of diaphragm on xiphisternum during development has been implicated.[21] Upper airway obstruction due to enlarged tonsils and adenoids predisposes to pectus excavatum.[22] Marfan's syndrome is associated with a high incidence of pectus excavatum. Incidence of congenital heart disease is also higher among those with pectus excavatum.

Most individuals with pectus excavatum remain asymptomatic, but for their cosmetic appearances. Dyspnea, out of proportion to the mild restrictive ventilatory defect may be seen. Majority of them have cardiac murmurs mimicking pulmonary stenosis caused by cardiac displacement. Chest radiographs frequently show a right paracardiac opacity due to parasternal soft tissues and should not be mistaken for middle lobe infiltration (Fig. 122.4).[20] Similarly, electrocardiogram may show abnormalities such as T-wave inversion in right chest leads, right axis deviation, P wave inversion in V1 and a QR pattern.[23]

More than 3 cm distance between anterior chest wall and the sternal depression and less than 10 cm distance between the posterior border of the sternum and the anterior border of the thoracic vertebra as seen on the lateral chest radiographs suggest severe deformity (Fig. 122.5). The degree of the deformity is measured by the computerized tomography scan as the ratio of transverse to anteroposterior diameter at the level of deepest sternal depression (Fig. 122.6). A ratio of more that 3.25 is considered to be severe excavatum.

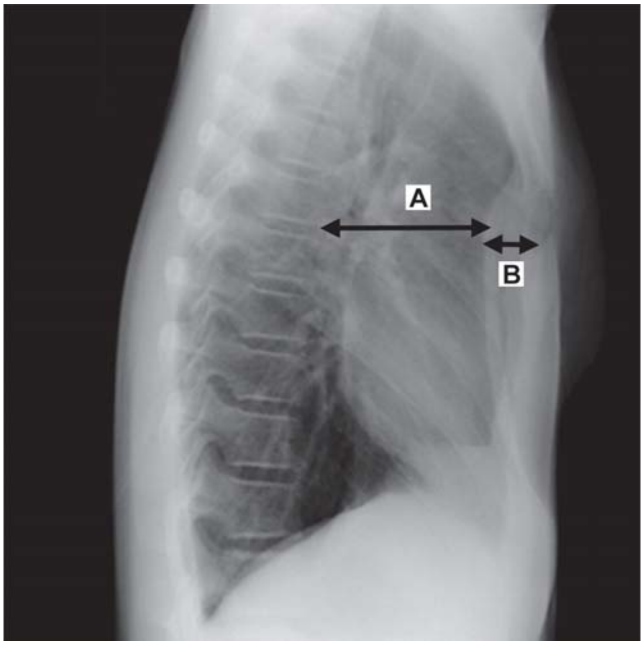

Fig. 122.5: Pectus excavatum: Chest radiograph—lateral view, < 10 cm distance between the posterior border of the sternum and the anterior border of the thoracic vertebra (A) and > 3 cm distance between anterior chest wall and the sternal depression. (B) suggests severe deformity (*Courtesy:* Dr Frank Gaillard, www.radiopedia.org, used with permission)

Pulmonary function tests are usually normal or mildly reduced in those with severe excavatum.[24,25] The reduced exercise tolerance out of proportion to lung function, can be attributed to reduced venous return secondary to right ventricular compression by the depressed sternum.

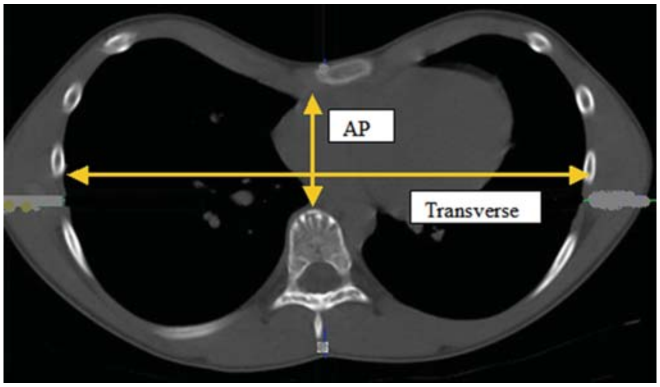

Fig. 122.6: Pectum excavatum: Ratio of transverse to anteroposterior diameter at the level of deepest sternal depression more than 3.25 suggests severe deformity

Patients with minimal deformity can benefit from a program of physical therapy to improve posture and the appearance of the chest. Surgery is necessary only in severe situations or for cosmetic purposes. The earlier surgeries like the Ravitch repair are associated with many complications.[26] Less invasive procedures like the Nuss procedure and sternochondroplasty, which were developed in the last decade, are relatively safer.[27,28] In the Nuss procedure, a curved bar is inserted behind the sternum to displace the sternum ventrally. These procedures are not always associated with improvement in pulmonary function or exercise capacity.

PECTUS CARINATUM

In this condition (also called "pigeon breast"), the sternum excessively protrudes anteriorly. It may be associated with other congenital anomalies especially cardiac lesions and coarctation of aorta.[29] Pectus carinatum may result from premature obliteration of the sternal sutures due to inadequate segmentation during fetal life or due to mal-attachment of diaphragm.[30] There is no functional defect with pectus carinatum and surgery is indicated only for cosmetic reasons.

ANKYLOSING SPONDYLOSIS

Ankylosing spondylosis (AS) belongs to a group of conditions having a strong association with HLA-B27 in which there is an inflammation of the axial skeleton. There is inflammation and bony ankylosis of vertebral structures, costovertebral and sternoclavicular joints, which leads to reduction in chest expansion. Chest expansion of less than 2.5 cm in a young adult at the level of fourth intercostal space along with back pain should raise the suspicion of AS. Exercise intolerance and dyspnea are uncommon, unless there is associated underlying lung fibrosis, diaphragmatic dysfunction or cardiac disease.

There is reduction in VC and TLC respectively to 70 and 80% of the predicted value. Since the rib cage is fixed during inspiration, the RV is increased leading to an increase in RV/TLC ratio.[31] Modest decrease in respiratory muscle strength is observed and it is attributed to the intercostal muscle atrophy, secondary to reduced rib cage mobility. About 1 to 4% of patients, especially men with chronic disease, develop fibrobullous upper lobe disease.[32] Apical fibrosis can be detected on high resolution computed tomography (CT) scan in about 90% patients.[33] The cause of apical fibrobullous changes is unknown. Various theories have been postulated which include diminished upper lobe ventilation due to chest wall rigidity, altered apical mechanical stress due to rigid thoracic spine, recurrent pulmonary infection due to impaired cough, and respiratory mechanics as a result of thoracic rigidity.[34] Aspergillomas may form in the cavities or bullae. Other rare complications include pleural effusion, pneumothorax, airway obstruction by cricoarytenoid joint ankylosis and amyloidosis of the lung.[35-37]

Treatment is focused on symptom relief and maintenance of posture and mobility. Physiotherapy to improve chest wall movements and breathing exercises are important. Use of tumor necrosis factor (TNF) antagonists have recently revolutionized the management of patients with AS.[38]

OBESITY

The prevalence of obesity is increasing worldwide. The body mass index (BMI) is positively associated with morbidity and mortality. An individual with a BMI between 18.5 and 24.9 kg/m^2 is normal; a BMI between 25 and 29.9 kg/m^2 is overweight, and a BMI greater than 30 kg/m^2 is obese. Those having a BMI of greater than 40 kg/m^2 (morbid obesity) are especially predisposed towards developing restrictive lung disease. Some investigators have concluded that Indians are more predisposed to develop obesity related complications due to their different body, genetic and metabolic composition.[39] According to the new guidelines released by the Union Health Ministry of India, a person having a BMI greater than 23 kg/m^2 would be considered overweight.[40]

The respiratory morbidity due to obesity can be considered under the following three categories:

1. Simple obesity (SO) with minimal effects on respiration,
2. Morbid obesity (MO) with eucapnic individuals having compromised pulmonary function, and
3. Obesity hypoventilation syndrome (OHS) with hypercapnia during the awake state. Obstructive sleep apnea can coexist with any of these conditions.

Pulmonary Function Tests

Forced vital capacity (FVC) and TLC are usually preserved in SO, but reduced in OHS. The fat in the chest wall and abdomen causes reduction in functional reserve capacity (FRC) with near normal RV (Fig. 122.7). This results in markedly reduced expiratory reserve volume

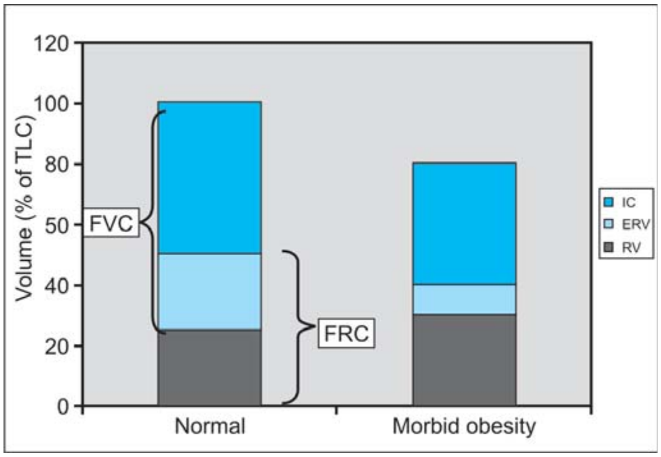

Fig. 122.7: Pulmonary function changes in obesity: Reduction in ERV with preservation of RV, Reduction in FVC

(ERV).[41] Similar degrees of obesity in SO and OHS can cause much more reduction in ERV in OHS due to difference in distribution of body fat. Even if FEV1/FVC ratio is normal, the specific conductance of airways is reduced to 50 to 70%, which is more evident in the supine position.[42] The cause of increased airway resistance in obesity appears to lie in the lung tissue and small airways rather than in the large airways. This leads to expiratory flow limitation and orthopnea.

Patients with OHS adapt to increased elastic and resistive loads by adopting rapid, shallow breathing pattern. The work of breathing and oxygen cost of breathing are markedly increased in OHS.[43] The increased oxygen consumption required for quiet breathing might place obese patients at risk of respiratory failure during conditions characterized by increased ventilatory demands, such as an intercurrent illness. Respiratory muscle strength is preserved in SO, but reduced in OHS due to deconditioning and fatty infiltration of muscles. This, along with disordered respiratory control and blunted respiratory drive, contribute to hypercapnia in OHS.

Severely obese patients tend to have a widened alveolar-arterial oxygen tension gradient and hypoxia. The mechanism responsible for hypoxemia is primarily a ventilation-perfusion mismatch that results from airway closure.[44] Hypoxia is also contributed by hypoventilation and venous admixture occurring in lung bases due to alveolar collapse.[45]

Treatment

Weight loss induced by either diet or surgery helps in improvement of ERV and hypoxia in patients with OHS. However, there is difficulty in losing weight and maintaining it in the majority of patients. In patients with OHS, noninvasive ventilation helps in improving gas exchange and daytime symptoms.

FLAIL CHEST

This is a condition in which fractures of ribs produce a segment of rib cage that moves paradoxically during respiration. Generally, double fractures of three or more contiguous ribs or a combination of sternal and rib fractures are required to produce a flail segment. The most common cause of flail chest is trauma due to fall or due to automobile accidents. Rarely, pathological fractures of ribs can cause a flail segment. During inspiration, the negative intrapleural pressure causes the flail segment to get displaced inward instead of expanding outward (Figs 122.8A and B). The most common site of flail segment is lateral chest wall, posteriorly. Respiratory failure caused by flail chest has a multifactorial etiology:

- Hypoventilation caused by paradoxical movement of flail segment and restricted chest wall movements due to pain. The VC and FRC may be reduced to 50% of the predicted value.
- Regional atelectasis caused by ineffective cough reflex and hypoventilation.
- Pulmonary contusion, hemothorax or pneumothorax, which is frequently associated with flail chest.
- Inspiratory muscle dysfunction due to muscle spasm and altered recruitment pattern causing increased work of breathing.

Treatment consists of adequate pain relief to prevent atelectasis and improve tidal volume. It can be achieved with medications, intercostal nerve blocks and epidural anesthesia. Stabilizing the flail segment by external strappings is not very successful. Positive pressure ventilation can provide effective stabilization by eliminating the negative intrapleural pressure. Earlier, mechanical ventilation was used for providing the ventilation. More recently, noninvasive continuous positive airway ventilation together with regional anesthesia has been found to reduce morbidity and avoid complications.[46] In case of severe injuries, a variety of surgical procedures have been described for fracture fixation and improvement of respiratory mechanics.

MISCELLANEOUS CONDITIONS

Cervical Ribs

Cervical ribs occur in about 0.5% of the population.[47] They arise from the seventh cervical vertebra and are

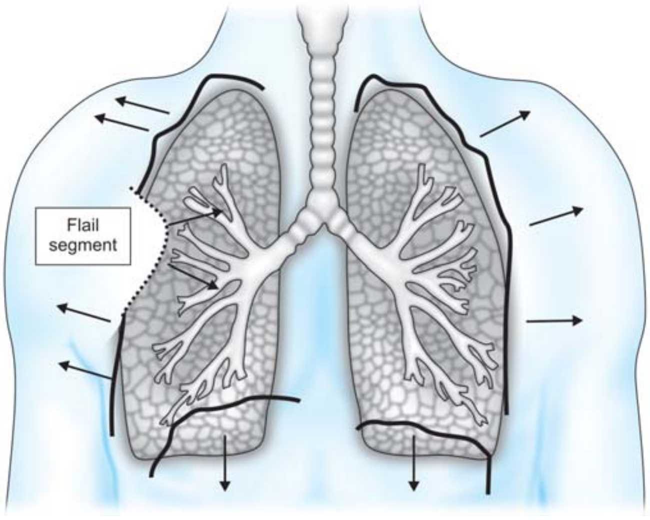

Fig. 122.8A: During inspiration the flail segment paradoxically moves inwards

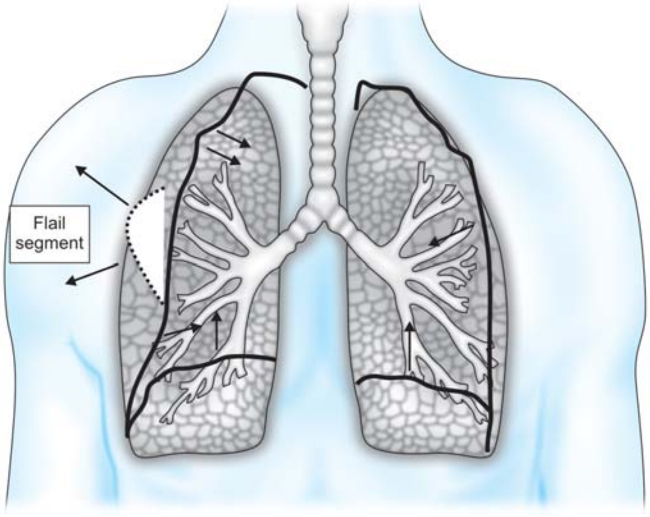

Fig. 122.8B: During expiration the flail segment moves outwards

bilateral in 80% cases (Fig. 122.9).[48,49] They are usually asymptomatic, but rarely can cause thoracic outlet syndrome due to compression of subclavian vessels or cervical nerve roots. The presence of symptoms is not dependent on the size of the rib, since the fibrous attachment itself may cause compression. While the neurological complications can be managed by shoulder muscle strengthening exercises, rib resection may be required to address the vascular complications.

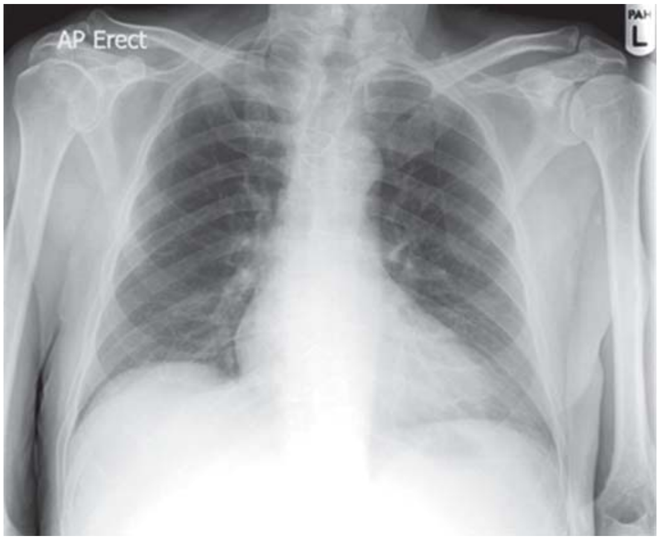

Fig. 122.9: Right cervical rib (Image courtesy: Dr Jeremy Jones, www.radiopedia.org, used with permission)

Tietze's Syndrome or Costochondritis

The etiology of this condition is unknown. It presents with pain and swelling of one or more of the upper six costal cartilages. It is more common in young adults with no sex predisposition and predominately affects the second costal cartilage. Coughing or deep breathing may exacerbate the pain. The condition may persist for weeks, months or years. Biopsy may show normal cartilage and there are no X-ray changes.[50] Ultrasonography shows thickened cartilage with inhomogeneously increased echogenicity, and hypoechoic halo, while CT scan may reveal thickened hypodense cartilage with blurred outline.[51,52] Recently, magnetic resonance imaging has been claimed to be the investigation of choice to reveal cartilage and bone abnormalities.[53] The main treatment consists of reassurance with or without administration of analgesics, to which the majority of patients respond. In those with severe pain, local steroid injection may be required.

Rib Notching

Erosion of the inferior border of ribs (inferior rib notching) is most commonly seen in patients with coarctation of aorta. It is due to the enlarged intercostal arteries, which through their pulsation cause erosion of ribs. The first two and the last three ribs are never involved.[54] Other causes of rib notching include subclavian artery obstruction, Takayasu's arteritis, pulmonary arteriovenous fistula and intercostal neuroma. Superior notching of third to sixth ribs is reported in patients with poliomyelitis and in those with connective tissue disorders.[55]

Tumors of the Chest Wall

Metastatic tumors of the chest wall are more common that the primary tumors. Lipoma and fibrosarcoma are the most common benign and malignant soft tissue tumors of the chest wall respectively. Osteochondroma and chondrosarcoma are the most common benign and malignant tumors of the bony thoracic skeleton respectively.

Tuberculosis of the Thoracic Cage

Costal cartilages, sternoclavicular and acromioclavicular joints can rarely be involved by tuberculosis. Multiple lesions of the costovertebral portions of the ribs may accompany tuberculosis of the spine with paravertebral abscess formation.

Cold abscess of the chest wall, which originates from tuberculosis of the intercostal lymph glands can be present at three sites:

1. Near the erector spinae muscles when pus tracks along the posterior primary division of the intercostal nerve;
2. Lateral chest wall, when pus tracks along the anterior division; and
3. Near costal cartilages.

Cold abscess commonly presents as a painless fluctuant swelling. Diagnosis is made by aspiration of the pus. Generally, it responds well to standard antitubercular chemotherapy.

Diseases of Diaphragm

Balamugesh T

INTRODUCTION

The diaphragm is a musculotendinous sheet that separates the thoracic and abdominal contents into two compartments. It has three anatomic components:

1. Sternal portion: Arising from the xiphoid process of sternum
2. Costal portion: Arising from lower six ribs
3. Crural portion: Arising from external and internal arcuate ligaments and attaching to vertebrae.

The muscle fibers from all these three components insert into the boomerang-shaped central tendon.

Excursion of the diaphragm is estimated to account for 60 to 75% of vital capacity, the remaining being contributed by the intercostal and accessory muscles.[1] During quiet respiration, the mean right and left hemidiaphragmatic excursions are 53 ± 16 mm and 46 ± 12 mm, respectively.[2]

The diaphragm receives its nerve supply solely from the phrenic nerve, which originates predominantly from the fourth cervical ramus with contributions from the third and the fifth ramus. Any damage to the phrenic nerve along its long course through the neck and mediastinum can affect its function.

Causes of Diaphragmatic Disorders

The causes of diaphragmatic disorders can be classified based on anatomical and neurological causes.

1. *Anatomical*
    a. Congenital: Bochdalek hernia, Morgagni hernia, eventration of the diaphragm and diaphragmatic agenesis
    b. Acquired: Traumatic.
2. *Neurological*
    a. Central nervous system: Brain stem stroke
    b. Spinal cord: Syringomyelia, anterior horn cell diseases, poliomyelitis, Arnold-Chiari malformation, tetanus, Strychnine poisoning.
    c. Nerves: Guillain–Barré syndrome, neuropathy due to variety of causes, invasion of phrenic nerve by neoplasm (most common cause), damage to nerve by surgery or trauma, infectious neuritis (e.g. herpes zoster).
    d. Muscles: Myasthenia Gravis, myopathy (muscular dystrophy, Duchenne muscular dystrophy, metabolic myopathy, connective tissue disorders (e.g. polymyositis, “shrinking lung syndrome” in SLE), acid maltase deficiency, etc.

Signs and Symptoms

The onset of presentation depends greatly on the etiology causing diaphragmatic dysfunction. Unilateral diaphragmatic paralysis is generally asymptomatic. Exertional dyspnea is present, when there is concomitant pulmonary parenchymal or airway disease. Bilateral diaphragmatic paralysis presents with severe exertional dyspnea and orthopnea. Poor quality sleep and day-time fatigue are also frequent.

Physical examination may reveal rapid shallow breathing. There may be paradoxical abdominal wall retraction during inspiration. Percussion may suggest a raised diaphragm and reduced diaphragmatic excursion during inspiration. The intensity of breath sounds may be reduced on the affected side, upon auscultation. The compressed lung may give rise to crackles, just above the area of paralyzed diaphragm.

Diagnosis

Chest Radiography

Posteroanterior radiographs show the dome of right hemidiaphragm projecting into a plane ranging from the anterior end of the fifth rib to the sixth anterior interspace in about 95% of normal individuals.[3] In most people, the right hemidiaphragm projects half an interspace higher than the left, being at the same level as or lower than the left hemidiaphragm in only about 10% cases.[4] Diaphragmatic paralysis manifests in the form of an elevated hemidiaphragm. Linear atelectasis may be present at the lung bases. Chest X-ray may also reveal a thoracic mass lesion, which is responsible for phrenic nerve paralysis or a congenital diaphragmatic hernia.

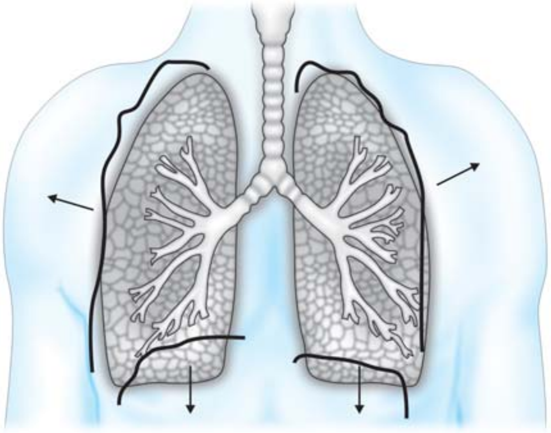

Fig. 123.1A: Normal inspiration. Chest wall moves outwards and diaphragm moves downwards

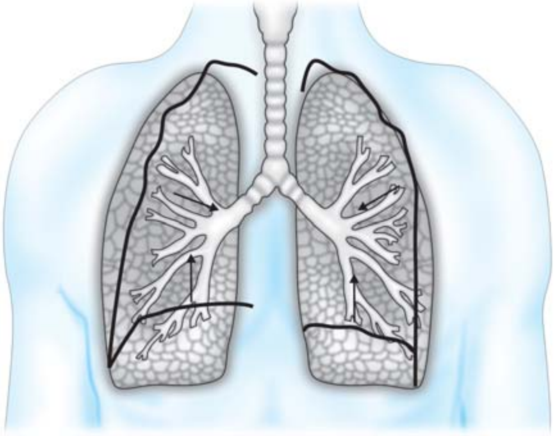

Fig. 123.1B: Normal expiration. Chest wall moves inwards and diaphragm moves upwards

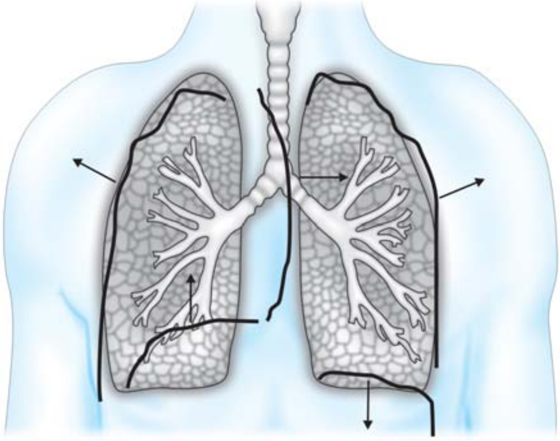

Fig. 123.1C: Right diaphragmatic palsy during inspiration: Paralyzed right diaphragm passively elevates in response to the more negative intrapleural pressure. The mediastinum shifts towards left

Fluoroscopy

Paradoxical upward movement of diaphragm by more than 2 cm on deep inspiratory effort against a closed airway ("sniff test") is suggestive of diaphragmatic paralysis.[5] However, in 6% of normal population, this can be found without any apparent reason. The cephalad movement of the paralyzed diaphragm during inspiration is accompanied by the outwards chest wall and the inwards abdominal wall motion, a phenomenon known as *thoracoabdominal paradox*.[6] Mediastinal swing found during respiration can be found in unilateral diaphragmatic palsy. In bilateral paralysis, sniff test may be misleading because of the cephalad movement of ribs, which may produce a false appearance of downward movement of diaphragm. Also, recruitment of abdominal expiratory muscles can cause a false-negative sniff test result. The movement of the diaphragm in normal, unilateral and bilateral diaphragmatic palsy can be schematically depicted (Figs 123.10 A to H).

Other Imaging Methods

Ultrasound scanning has been found to be more reliable than fluoroscopy in the evaluation of diaphragmatic movements. Ultrasound measurement of the thickness of the diaphragm can be used to determine if the diaphragm is paralyzed.[7] Computed tomography (CT) scan is helpful for identifying the presence of any mass lesion along the course of phrenic nerve causing the paralysis.

Pulmonary Function Tests

Restrictive ventilation defect is seen in patients with diaphragmatic paralysis. In unilateral paralysis, forced

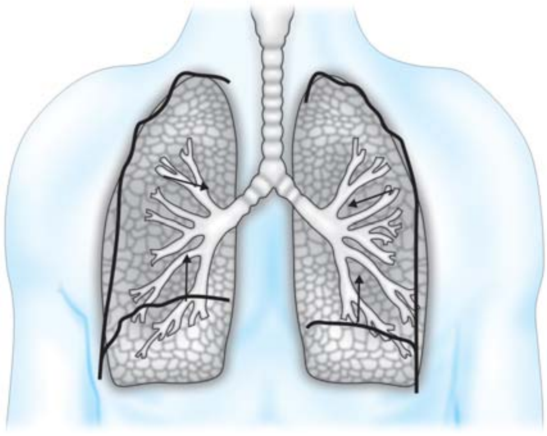

Fig. 123.1D: Right diaphragmatic palsy during expiration: On full expiration, a rise in intra-abdominal pressure evokes an even greater elevation

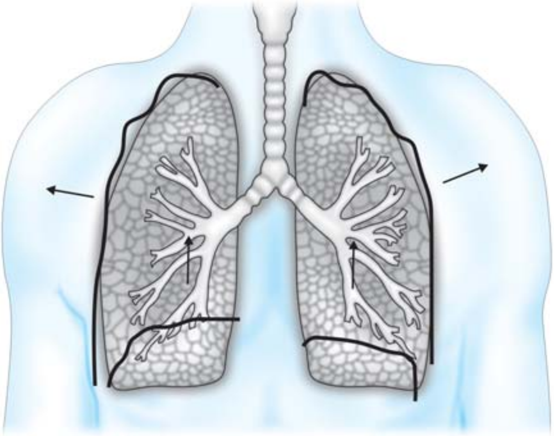

Fig. 123.1E: Bilateral diaphragmatic palsy on inspiration: On inspiration, the increased negative intrapleural pressure "sucks" both the diaphragms up and draws the abdominal wall in

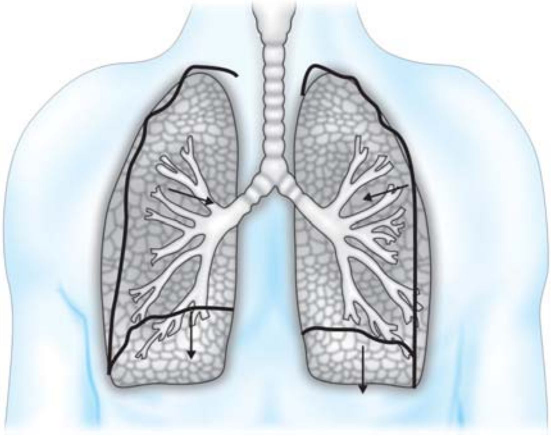

Fig. 123.1F: Bilateral diaphragmatic palsy on expiration to functional residual capacity (FRC): Diaphragm descends and the abdomen protrudes

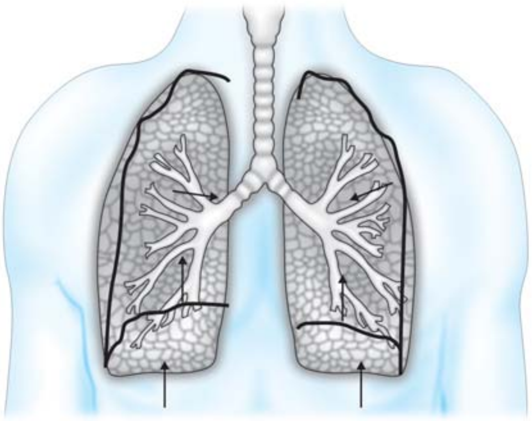

Fig. 123.1G: Bilateral diaphragmatic palsy on expiration to RV: On deeper expiration, there is active contraction of abdominal muscles and the diaphragm rises

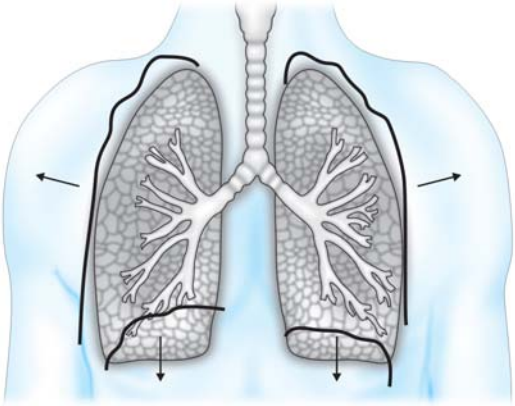

Fig. 123.1H: Bilateral diaphragmatic palsy early inspiration to FRC: Abdominal muscles relax associated with descent of the flaccid diaphragm, creating the false impression of active contraction

vital capacity (FVC) is reduced to about 75% of the predicted value, and the total lung capacity (TLC) is about 85% of predicted.[8] A 10% decrease in vital capacity (VC) in the supine position is typically present in normal individuals. In unilateral diaphragmatic weakness, the fall in VC is much more pronounced in supine position.[9] The maximal inspiratory pressure ($P_{I\text{-max}}$) decreases to a value of 60% predicted.[10] In patients with bilateral diaphragmatic paralysis, FVC is reduced by 50% and TLC by 55%.[11] The $P_{I\text{-max}}$ is less than 60 cm water.

Electrophysiological Studies

Phrenic nerve conduction studies are useful for detecting neurological causes of paralysis. Electromyograph of diaphragm and phrenic nerve stimulation studies help in the diagnosis of myopathic conditions involving the diaphragm.

Transdiaphragmatic pressure measurements can accurately quantify the degree of diaphragmatic weakness by measuring the difference between intragastric and intrapleural pressure. During normal inspiration, gastric pressure becomes more positive and esophageal pressure becomes more negative. In unilateral diaphragmatic paralysis, gastric pressure becomes more negative during inspiration, although to a lesser extent than the negative swing in esophageal pressure. In bilateral diaphragmatic paralysis, during tidal breathing, gastric pressure decreases to the same extent as esophageal pressure, resulting in no active transdiaphragmatic pressure generation.[12]

Management

Treatment of diaphragmatic dysfunction depends on the etiology. Surgery is indicated in the management of anatomic defects of the diaphragm. Most patients with bilateral diaphragmatic paralysis ultimately develop progressive ventilatory failure resulting from fatigue of the accessory muscles. These patients usually require non-invasive ventilation. Indications for non-invasive ventilation in neuromuscular disease are described in table 123.1.[13]

Phrenic nerve or diaphragmatic pacing are useful treatment modalities when the phrenic nerve is intact and the problem lies in the actual transmission of nerve impulse.[14]

Disorders of the Structure of Diaphragm

Eventration of Diaphragm

Eventration is a condition in which all or part of the diaphragm is largely composed of fibrous tissue with only a few interspersed muscle fibers. It is usually congenital. Complete eventration mostly occurs on the left side and is characterized by the elevation of left diaphragm. This hemidiaphragm may move paradoxically during "sniff test". The adult patients are usually asymptomatic, but occasionally they have dyspeptic symptoms. Dyspnea is common if eventration is associated with other lung diseases. In infants, eventration may occur on either side and can give rise to severe respiratory distress. Plication of the diaphragm is performed to keep the diaphragm in its normal position.[15]

TABLE 123.1: Indications for noninvasive ventilation in neuromuscular disease

Optimal non-ventilatory therapy of symptoms
and
Gas exchange abnormalities, which can be one of the following:

- Daytime hypercapnia ($pCO_2 > 45$)
- Nocturnal hypoventilation (O_2 sat < 88% for > 5 consecutive minutes)
- FVC < 50% predicted or maximal inspiratory procedure < 60% predicted

Other possible indications: Repeated hospitalizations for respiratory failure, and cor pulmonale.

Partial eventration occurs exclusively on the right side. It manifests as an anteromedial bulge of the diaphragm that moves downwards during inspiration with normal portions of the hemidiaphragm, but with some delay.[16] There is usually an accessory lobe of liver, which occupies the bulge.[17]

Diaphragmatic Hernias

It can present at various sites of the diaphragm (Fig. 123.2):

1. *Hiatus hernia:* Herniation through the esophageal hiatus is the most common type of diaphragmatic hernia. It may predispose to gastroesophageal reflux disease and can appear as a retrocardiac opacity with a fluid level on chest radiograph (Figs 123.3A and B).
2. *Bochdalek hernia:* The hernia is at the posterolateral part of the diaphragm and is the most common site for congenital diaphragmatic hernia.[18] The majority of patients present with respiratory distress immediately after birth. The mortality rate is 45 to 50%. It is more common on the left side and may be

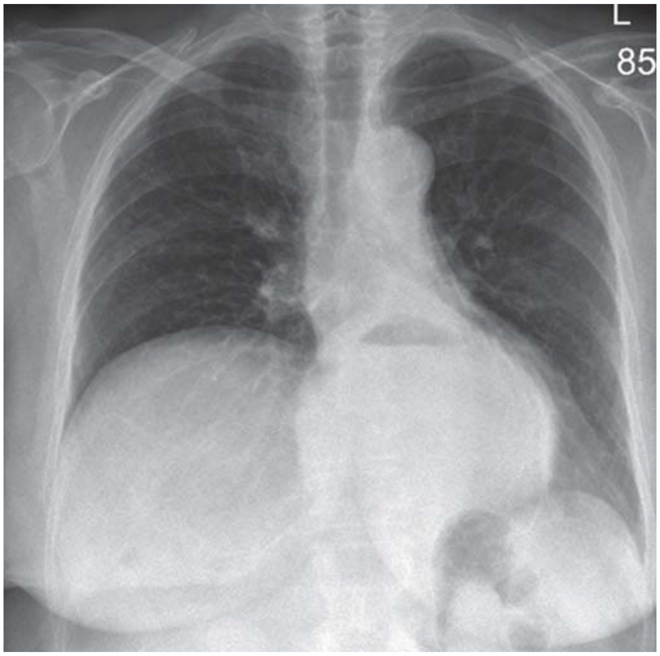

Fig. 123.3A: Hiatus hernia. Chest radiograph showing retrocardiac fluid level

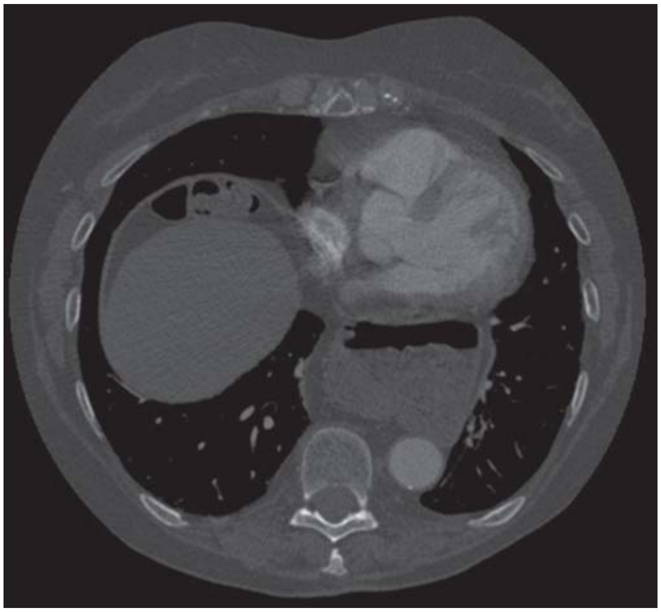

Fig. 123.3B: CT scan of the same patient showing stomach in the posterior mediastinum

associated with central nervous system anomalies and lung hypoplasia. X-ray examination reveals absence of diaphragm on the affected side and presence of abdominal contents in the thorax (Fig. 123.4). Presentation in adulthood is uncommon.[19]

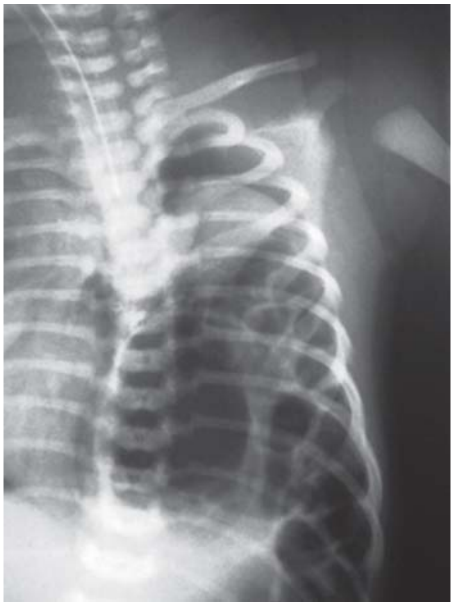

Fig. 123.4: Congenital diaphragmatic hernia. Absent diaphragm on the left side with presence of abdominal contents in the thorax. (Image courtesy: Dr Pradeep A Wijayagoonawardana, www.radiopedia.org, used with permission)

3. *Morgagni hernia:* Foramen of Morgagni is present anteromedially and is usually filled with loose connective tissue, but abdominal contents may herniate through the foramen, more commonly on the right (Fig. 123.2). Presentation in childhood is rare.[20] Chest X-ray shows as a rounded opacity in the cardiophrenic angle that may or may not contain gas.

Post-polio Syndrome (PPS)

Post-polio syndrome is a neurological disorder that produces a cluster of symptoms occurring in 22 to 64% of patients, 30–50 years after an attack of acute paralytic poliomyelitis.[21] The symptoms include the presence of progressive weakness, fatigue and less commonly muscle atrophy; breathing and swallowing difficulties; and sleep disorders. The criteria for diagnosis of PPS include documentation of paralytic polio, partial recovery of function followed by a period of stabilization, and progressive neurological deterioration.[22]

Respiratory insufficiency, which occurs in about 40%, is more common in those who had respiratory failure during the acute stage.[23] It usually results from respiratory muscle weakness with central hypoventilation and scoliosis.[24] Risk factors, which contribute to PPS, include severe initial episode, older age at initial episode, greater recovery from the first episode and over use of muscles.[25,26] Initially, respiratory failure manifests as nocturnal hypoventilation and then it progresses. Electromyography and muscle biopsy may show characteristic findings. The etiology is unknown, although premature exhaustion of the new sprouts that develop after acute poliomyelitis and of their motor neurons are important factors.[27] Other possible contributory factors include persistent poliovirus infection and an immune-mediated process. Treatment is primarily supportive and includes noninvasive ventilation, when required. Non-fatiguing strengthening exercises can improve strength and provide short-term benefit.

Syndromes of Inappropriate Respiratory Muscle Contraction

These disorders share some common features like inappropriate timing, asynchronous activity, or excessive contraction of respiratory muscles (Table 123.2).

1. *Hiccups:* Hiccups are produced by short, sharp contractions of the diaphragm and inspiratory intercostal muscles, coupled with transient closure to the glottis, which can occur upto 10 to 30 times per minute.[28]

Causes

a. Central nervous system: Multiple sclerosis, meningitis, encephalitis, cerebrovascular causes, brain tumor, post cranial surgery
b. Metabolic: Uremia, hyponatremia
c. Drugs: Alcohol intoxication, dexamethasone
d. Nerve irritation (vagus or phrenic nerve): Herpes zoster infection, inflammatory or neoplastic lesions of the mediastinum
e. Gastrointestinal: Esophageal irritation (neoplasm/ stent/ infection), stimulation of the diaphragm and/ or stomach by heat, cold, spasm, dilation, and distention.

TABLE 123.2: Syndromes of inappropriate respiratory muscle contraction

Syndrome	*Type of respiratory muscle involvement*
Hiccups	Spasmodic contraction of diaphragm and other inspiratory muscles
Respiratory myoclonus (tic, flutter of diaphragm)	Spasmodic contraction of diaphragm
Respiratory dyskinesia	Abnormal asynchronous pattern of breathing associated with neurocirculatory asthenia
Convulsive disorders	Status epilepticus, tetanus, strychnine poisoning

TABLE 123.3: Treatment of hiccups

General measures	*Drugs*
Stimulate the throat • Quickly swallow two heaped teaspoons of sugar, drink cold water or eat crushed ice, or rub with a clean cloth inside the top of the mouth. • Rapid pharyngeal stimulation with a nasogastric tube *Interrupt normal breathing* • Hold breath or breathe into paper bag • Pull knees to chest and lean forward (compress the chest)	The choice of drug should depend on the probable cause of hiccup. Metoclopramide Haloperidol Baclofen Chlorpromazine Anticonvulsants (Carbamazepine, Gabapentin) Calcium channel blocker

The pathogenesis of hiccups is unclear but seems to relate to supraspinal mechanism and reflex arcs. Numerous treatments for hiccups are described (Table 123.3)[29,30] Pharmacological therapy should be tried for those with persistent hiccup.

2. *Myoclonus:* Respiratory myoclonus (Leeuwenhoek's disease) is a rhythmic repetitive contraction of respiratory muscles, at a frequency of 30-300/min.[31] The pathogenesis is not clear, though some nervous system dysfunction at the level of the brain, spinal cord or phrenic nerve has been postulated. It is associated with palatal myoclonus.

Diffuse Alveolar Hemorrhage Syndromes, Wegener's Granulomatosis and Other Pulmonary Vasculitis

Eleni Stagaki, Vlasis Polychronopoulos

DIFFUSE ALVEOLAR HEMORRHAGE SYNDROMES

Diffuse Alveolar Hemorrhage (DAH) is a potentially life-threatening clinicopathological syndrome characterized by intralveolar bleeding, caused by the disruption of the pulmonary capillary lining due to a variety of conditions.[1,2] Hemoptysis, diffuse alveolar infiltrates and a drop in hematocrit consist the characteristic triad of DAH manifestations. Hemoptysis may be absent in upto one-third of the patients with Alveolar Hemorrhage (AH) and the severity of symptoms and signs—dyspnea, hypoxemia and cough associated with fever—depend on the extent of underlying disease. Therefore, DAH may be subclinically suspected when chest radiograph demonstrates new unexplained bilateral alveolar infiltrates in the face of falling hemoglobin and a hemorrhagic sequential Bronchoalveolar Lavage (BAL), in which sequential aliquots appear bloodier. The percentage of siderophages among the total alveolar macrophages recovered by BAL reported to indicate AH is atleast 25% in active DAH, even if the macroscopic appearance is not hemorrhagic.[3,4,5]

A number of distinct disorders can cause DAH. The identification of the underlying cause and prompt implementation of appropriate therapy is crucial for a patient presenting with DAH. The differential diagnosis of DAH includes diseases associated with the pathological finding of capillaritis (a cellular infiltrate of neutrophils in the capillaries and venules; and those associated with normal vessels, or bland hemorrhage (Table 124.1).

Diagnosis and Evaluation

The priority for DAH diagnosis is to first exclude other conditions that can be similar from the clinical and radiological point of view. Smoking-related micro-hemorrhage, congestive heart failure, pleural biopsy, vasculitis due to infection in immunocompromised host and hemosiderosis. Pulmonary alveolar hemorrhage may also be associated with thrombocytopenia (<50,000 cells/μL), other abnormal coagulation syndromes and renal failure.

Clinical Evaluation

The medical history should include all the pre-existing conditions that can cause AH (coagulopathy; mitral stenosis; recent bone marrow transplantation; pre-existing autoimmune disorders; drugs like penicillamine, propylthiouracil, cytotoxic drugs, amiodarone mito-mycin; all-trans retinoic acid; smoking history; and exposure to inhalation toxins, such as trimellitic anhydride or drug abuse, including crack cocaine abuse).

Clinical evaluation should include search for abnormalities suggesting systemic involvement. These include sinusitis, dermatological leukocytoclastic vasculitis, iridocyclitis, synovitis and glomerulonephritis.

Chest Radiography

The Chest Radiograph (CXR) or High-Resolution Computed Tomography (HRCT) are nonspecific and indicate air space disease that can be either patchy or diffuse in appearance. The presence of Kerley B lines on the chest radiograph suggests either another cause of diffuse alveolar hemorrhage (such as pulmonary veno-occlusive disease, mitral stenosis, or possibly pulmonary edema due to myocarditis, which can potentially complicate a systemic vasculitis or collagen vascular disease).

TABLE 124.1: Causes of Diffuse Alveolar Hemorrhage

Histological Findings of Capillaritis

- Primary idiopathic small vessel vasculitis
- Wegener's granulomatosis
- Churg-Strauss syndrome
- Microscopic polyangiitis
- Isolated pauci-immune pulmonary capillaritis
- Primary immune complex–mediated vasculitis
- Goodpasture's syndrome
- Henoch-Schönlein purpura
- Secondary vasculitis
- Classic autoimmune disease
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Antiphospholipid antibody syndrome
- Mixed connective tissue disease
- Polymyositis/dermatomyositis
- Essential cryoglobulinemia
- Behçet's disease
- Lung transplantation
- Bone-marrow transplantation
- Drug-induced (e.g. chemotherapeutic agents, propylthiouracil).

Absence of Capillaritis (Bland Hemorrhage)

- Idiopathic pulmonary hemosiderosis
- Coagulopathy
- Mitral stenosis
- Inhalation injury
- Goodpasture's syndrome
- Systemic lupus erythematosus
- Bone marrow transplantation (associated with diffuse alveolar damage)
- Drug-associated disease (e.g. chemotherapeutic agents).

Hematological Investigations

Initial blood testing should include complete blood count (CBC), chemistry group, coagulation status and baseline markers of inflammation [ESR (erythrocyte sedimentation rate and C-reactive protein)]. A urinalysis should always be ordered, because renal involvement is very often associated with pulmonary capillary disease. The typical finding consists of glomerular erythrocytes (usually in abundance) associated with proteinuria. The underlying pathology may be either a segmental necrotizing glomerulonephritis rapidly progressing to renal failure [Wegener's granulomatosis (WG), microscopic polyangiitis (MPA)] or other systemic vasculitides or even may be pauci-immune idiopathic glomerulonephritis (Goodpasture's syndrome). In addition to serology testing, including Anti-Neutrophilic Cytoplasmic Antibodies (ANCA), anti-GBM antibodies, antinuclear antibodies (ANA), anti-dsDNA antibodies, antiphospholipid antibodies, rheumatoid factor (RF), creatinine kinase and complement levels should be ordered to find out the underlying disorder.

Diffusion Capacity

Most patients with DAH are too ill to undergo pulmonary function testing. However, measurements of the carbon monoxide transfer coefficient corrected for lung volume (KCO) may show sequential increases over time because of the heightened availability of intra-alveolar hemoglobin for combination with carbon monoxide.

Histopathological Diagnosis

Although diagnostic biopsy remains the gold standard, there are some cases where a confident diagnosis can be made without tissue biopsy. So, the decision to obtain biopsy specimen (renal, lung, other site-skin, upper airway, etc.) should be made taking into consideration the risk of the procedure and the likelihood of biopsy findings to alter the therapeutic approach. When the lung is clinically involved, surgical lung biopsy almost always provides definitive pathological evidence. It should be kept in mind that DAH recurrence may lead to interstitial fibrotic lesions; pathology may also reveal areas of organizing pneumonia and this does not exclude DAH diagnosis.

Renal biopsy is preferred as more convenient. In typical cases with multiple organ involvement, biopsy site could be skin, nose, etc. for WG, or even be avoided if serology is compatible (ANCA for MPA or WG, ANA for Systemic Lupus Erythematosus (SLE), anti-GBM for Goodpasture's syndrome). Video-Assisted Thoracoscopic Surgery (VATS) is preferred from open lung biopsy as it is associated with less morbidity and mortality. At the time of surgery, some tissue should be frozen (for immunofluorescence studies), fixed in formalin (for hematoxylin-eosin and special stains), and placed in a saline solution for culture. Because of the variety of testing performed on the samples, the processing should be closely coordinated among the physicians and surgeons involved, and the pathologist should be alerted that vasculitis is in the differential diagnosis.

Percutaneous renal biopsy is commonly performed during the evaluation of an acute glomerulonephritis. Although features specific for vasculitis (e.g. granulomatous inflammation or necrotic vessels) are rarely found, the finding of a focal, segmental necrotizing glomerulonephritis without immune deposits (pauci-immune) generally reflects a systemic vasculitis.[5] It is important that in addition to conventional histopathology, immunofluorescence (and electron microscopic when appropriate) studies to be performed. The presence of characteristic immunofluorescence patterns, such as IgA deposition in Henoch-Schönlein purpura, linear IgG deposition in Goodpasture's syndrome, and irregular immunoglobulin and complement deposition in SLE, help provide a specific diagnosis.

However, the clinician should not wait for the laboratory or biopsy results to begin treatment, with high doses of steroids and cytoxan, when vasculitis is highly suspected from clinical findings (dyspnea, pale face, highly desaturated patient), HRCT (alveolar filling disease, rapidly moving consolidations) and simple laboratory tests (drop of hematocrit and glomerular erythrocytes in urine).

WEGENER'S GRANULOMATOSIS AND OTHER PULMONARY VASCULITIDES

Pulmonary vasculitis comprises a heterogeneous group of disorders associated with prominent inflammation and/or necrosis of the vessels of different sizes. Vasculitis can be separated into primary and secondary vasculitis. The majority of primary vasculitides are idiopathic in origin. Their wide spectrum of frequently overlapping clinical manifestations is defined by the size and location of the affected vessels, as well as by the nature of inflammatory infiltrate. In secondary vasculitides, there is usually an underlying disorder such as collagen vascular diseases, immunological abnormalities, infection, drugs and neoplasm.

The nomenclature that most experts have adopted in classifying "primary pulmonary vasculitides" is that of Chapel Hill Consensus Conference in 1992.[6]

Most current classification schemes of vasculitides are based on clinicopathological features shown in Table 124.2.

TABLE 124.2: Classification of the vasculitides

Primary Idiopathic Vasculitis

Small Vessel

- Wegener's granulomatosis
- Churg-Strauss syndrome
- Microscopic polyangiitis
- Idiopathic pauci-immune rapidly progressive glomerulonephritis
- Isolated pauci-immune pulmonary capillaritis.

Medium Vessel

- Polyarteritis nodosa
- Kawasaki disease.

Large Vessel

- Giant cell arteritis
- Takayasu's arteritis
- Primary immune complex–mediated vasculitis
- Goodpasture's syndrome
- Henoch-Schönlein purpura
- Behçet disease
- IgA nephropathy.

Secondary Vasculitis

- Classic autoimmune disease
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Scleroderma
- Antiphospholipid antibody syndrome
- Essential cryoglobulinemia
- Inflammatory bowel disease
- Hypocomplementemic urticarial vasculitis
- Drug-induced (e.g. propylthiouracil, diphenylhydantoin)
- Paraneoplastic.

Lung involvement is most commonly seen with the primary, idiopathic, small-vessel, or antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides, as Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome. However, primary idiopathic medium and large-vessel vasculitis, primary immune complex–mediated vasculitis, and secondary vasculitis may also involve the lung.

Epidemiology

Pulmonary vasculitis is an uncommon condition and even Wegener's granulomatosis, perhaps the best known pulmonary vasculitis is rarely encountered in clinical practice. The estimated incidence is 20 to 100 cases/million and a prevalence of 150 to 450/million.[7] They can occur in people of all age groups, although the granulomatous vasculitides show a predilection for patients in their fifth and sixth decades and anaphylactoid purpura is more common among young children. The multicenter study by the American College of Rheumatology (ACR) of 1,020 patients of North America in 1990 estimated the incidence of various vasculitides as follows. A total of 807 satisfied the criteria for the diagnosis of the following types of primary vasculitides: giant-cell (temporal) arteritis (GCA) 27%, polyarteritis nodosa (PAN) 15%, Wegener's granulomatosis (WG) 11%, Henoch-Schönlein purpura (HSP) 10.5%, Takayasu arteritis 8% and Churg-Strauss (CSS) 2.5%.The rest 213 patients had secondary vasculitis mainly due to collagen diseases.

Specific Disorders

ANCA - Associated Vasculitides

The three primary systemic small vessel vasculitides are Wegener's granulomatosis (WG), microscopic polyangiitis (MPA) and Churg Strauss (CSS) syndrome, which is the rarest of the three. Most patients with active WG and MPA and 40 to 70% of patients with CSS are ANCA positive (either p- or c-, sometimes both). Respiratory manifestations of ANCA associated vasculitides are much more common compared to all other systemic vasculitides.

Wegener's granulomatosis (WG): The Chapel Hill Consensus nomenclature has defined WG as the "granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels (i.e. capillaries, venules, arterioles and arteries)." The incidence of the disease is estimated upto 8.5/million (range 5.2 to 12.9/million) with a male-to-female ratio of 1:1. The disease usually involves Caucasians (80–97%) with a mean age at the time of diagnosis of 40–55 years, although any age may be affected.[8]

The most common presenting symptoms are related to the **upper respiratory tract.** These include nasal obstruction, serosanguinous secretion, epistaxis and destruction of nasal cartilage leading to saddle-nose deformity, ulcerative stomatitis, gingivitis, external ear chondritis, otitis media and mastoiditis. *Staphylococcus* is frequently detected in the nose and sinuses and has been linked to relapses of the disease.[9] **Airway involvement** is found in 15 to 55% of patients. Subglottic stenosis is the most frequent airway manifestation in WG. It is more often in young women and can cause life-threatening compromise of the airway.[10] A high index of suspicion is important in detecting this lesion as it is not related with disease extent and activity may be the only manifestation for the first year. Twenty percent of WG limited to respiratory tract (without AH) is ANCA-negative. It has nonspecific presenting symptoms (dyspnea, cough, voice changes) and is often treated as asthma. Although subglottic disease is optimally diagnosed by otolaryngological visualization, an extrathoracic obstruction may be suggested by changes in the flow-volume loop (Fig. 124.1).

Similarly significant mucosal inflammation and ulceration or fibrotic scarring can occur at any level of the tracheobronchial tree. Usually the disease is not detected at this early stage where upper respiratory tract is involved and patients are treated as chronic sinusitis. Every patient with such symptoms has to be thoroughly checked with chest CXR and simple ENT exams for the severity of Wegener disease.

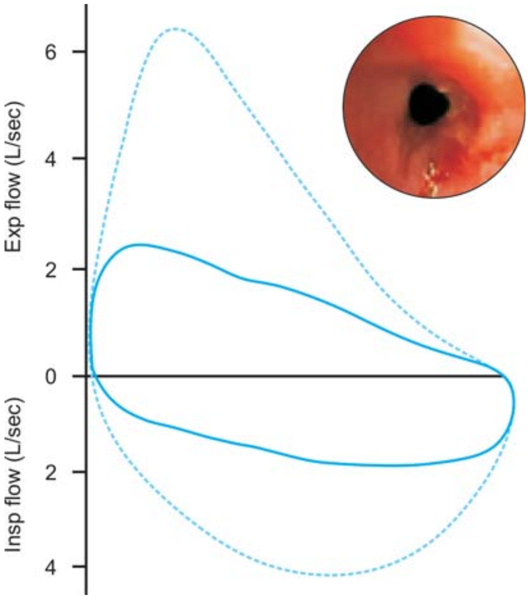

Fig. 124.1: Flow-volume tracings in a patient with significant midtracheal stenosis (inset) show typical features of a fixed major airway obstruction with flattening of both the inspiratory and expiratory flow-volume curves. Interrupted lines show predicted normal tracing[11]

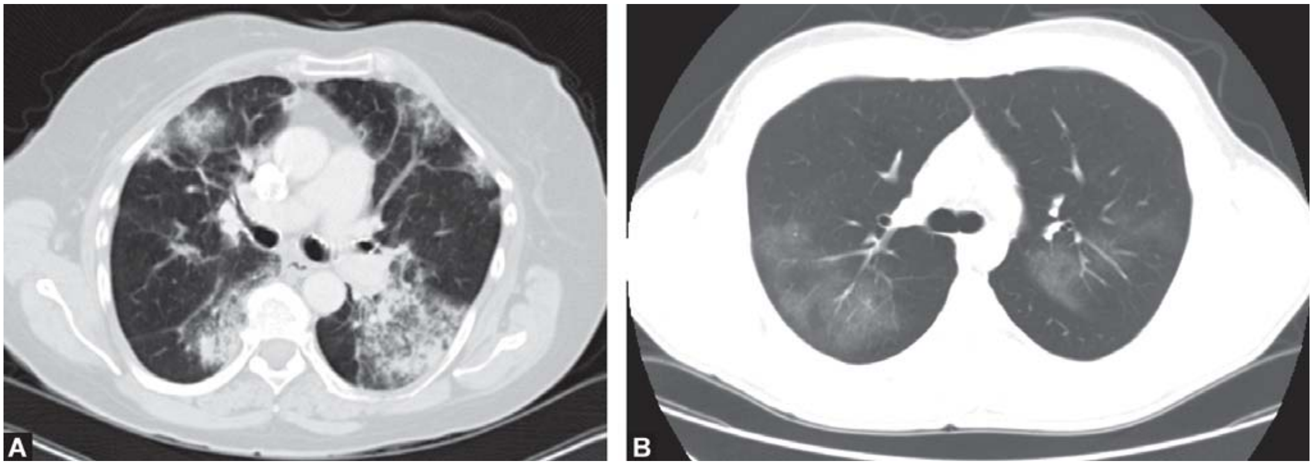
Pulmonary involvement occurs at some stage of the disease in almost all patients, and chest radiographic abnormalities are presented in upto 85%.[11] Computed tomography is superior to chest radiography in assessing the presence and extent of pulmonary parenchymal abnormalities in patients with WG (Figs 124.2A and B). Solitary or multiple nodules or masses, that are cavitated in as many as 50% of patients, are the most common findings in the lungs. Airspace opacities are a second manifestation of Wegener's granulomatosis. Usually, these opacities with or without cavitating nodules involve a localized region and may present areas of consolidation with some hyperlucent regions, which mimic a lung abscess or lung cancer. These diffuse alveolar opacities most frequently are the result of pulmonary hemorrhage. Even at this stage the correct diagnosis may be missed and patients are treated as if they had pneumonia or lung cancer because of the presence of fever, cough, hemoptysis and endobronchial findings. Other less common pulmonary manifestations include atelectasis, reticular interstitial opacities, pleural abnormalities and mediastinal adenopathy.

Glomerulonephritis is one of the most serious disease manifestations of WG as it can progress rapidly



Figs 124.2A and B: Computed tomography appearance of alveolar hemorrhage . (A) and (B) Two representative images obtained from a patient with known Wegener's granulomatosis. Figure (A) shows how subtle the infiltrates can be

to complete renal failure in the absence of symptoms. Continued vigilance for glomerulonephritis is essential as it is present at diagnosis in only 20% of patients, but develops in 80% of patients at some point during the course of their disease. Renal disease manifests as crescent necrotizing glomerulonephritis characterized by urinary sediment with more than 5 RBCs per high-power field (HPF) or erythrocyte casts (early stage) and potentially a decline in renal function as evidenced by a rise in serum creatinine or a decrease in creatinine clearance (late stage).

Patients may report chronic, nonspecific constitutional complaints: fevers, night sweats, fatigue and weight loss. **The skin** is involved in 45% of patients with WG due to leukocytoclastic vasculitis and can lead to palpable purpura or skin ulcers. **The nervous system** is affected by vasculitis in 22% of patients. Clinical manifestations include mononeuritis multiplex and cranial nerve abnormalities. Large joint **arthritis**, polyarticular symmetric small and medium joint arthralgias, and myalgias may be found. **Ocular** findings include scleritis, keratitis, uveitis, episcleritis and conjunctivitis. **Cardiac** and **gastrointestinal** systems can rarely be involved in WG (Table 124.3).

Classification criteria have been developed by the American College of Rheumatology (ACR) for WG. **In the presence of vasculitis,** atleast two of the following criteria should be met for the purpose of classification of vasculitis as WG: (1) nasal or oral inflammation—defined as the development of painful or painless ulcers or purulent or bloody nasal discharge; (2) abnormal chest radiograph—the presence of cavitating or noncavitating nodules or fixed infiltrates; (3) an abnormal urinary sediment—microscopic hematuria with >5 red blood cells/high power field or red casts in the urine sediment; and (4) granulomatous inflammation—histological changes showing granulomatous inflammation within the wall of an artery or arteriole or in the perivascular or extravascular area on a biopsy specimen. The presence of any two or more criteria yields a sensitivity of 88.2% and a specificity of 92%.

ANCA

Three indirect immunofluorescent staining patterns, cytoplasmic ANCA(C-ANCA), perinuclear ANCA (P-ANCA), and atypical ANCA are described. ANCA that causes a cytoplasmic immunofluorescence pattern (C-ANCA) on ethanol-fixed neutrophils are caused by antibodies reacting with proteinase 3 (PR3-ANCA).[12] In contrast, a variety of antibodies can cause a perinuclear immunofluorescence pattern (P-ANCA) on ethanol-fixed neutrophils.

Only the PR3-ANCA with C-ANCA combination and the MPO-ANCA with P-ANCA combination are sensitive and specific for ANCA-associated vasculitides (AAV).[13] Positive and negative predictive values of ANCA testing for WG and MPA, are critically dependent on the pretest probability of the disease in the patient tested, as well as on the analytical accuracy of the test method. It is important to recognize that most patients with active severe disease are ANCA positive, but about 25% with limited WG have no detectable ANCA. C-ANCA is highly sensitive (90–95%) in active, systemic WG, with a specificity of approximately 90%. In the proper clinical setting (i.e. with a very high pretest

TABLE 124.3:Clinical Characteristics of the ANCA-Associated Vasculitides[42]

Variables	*WG*	*MPA*	*CSS*
Pulmonary	Very common, 70–95% of patients; symptoms may include cough, chest pain, dyspnea, or hemoptysis; Tracheobronchial and endobronchial disease also relatively frequent (10–50%)	Moderately common with 10–30% of patients experiencing involvement, most of which demonstrate alveolar hemorrhage	Asthma is essentially universal; patients may also have infiltrates/ eosinophilic pneumonia
Renal	RPGN occurs in 50-90% of patients	RPGN is essentially universal	RPGN occurs in 10–50% of patients
Upper Airway	Very common, 70–95% of patients; ulcerating and destructive lesions are suggestive	Variable	Sinusitis occurs in 20–70% of patients but often lacks the destructive nature seen in WG
Constitutional	Common; symptoms may include fatigue, malaise, fevers, and weight loss	Very common and often precedes RPGN	Common
Musculoskeletal	Arthralgias, arthritis and myalgias occur in approximately one half of patients	Arthralgias and myalgias in atleast one half of patients	Arthralgias and myalgias reported in up to one half of patients.
Ocular	Common, occurring in 25–50% of patients; sight-threatening disease including uveitis, ocular ulcers, alongwith a host of other complications may occur	Less common, 0–30% of patients	Uncommon
Cardiac	5–15%	10–20%	Common (30–50%) and a major cause of mortality in patients with CSS; may present with conduction delay, other ECG abnormality, systolic or diastolic dysfunction, or coronary artery involvement
Gastrointestinal	Uncommon	Common, 35–45%; complications usually resemble those of the other ANCA associated vasculitides (see CSS), although it is possible to see the visceral aneurysms most commonly associated with classic polyarteritis nodosa	Common (30–60%); another major cause of morbidity and mortality; may present with hemorrhage, abdominal pain, infarct, or perforated viscous.
Dermatological	Common; may include classic palpable purpura, but may also present with ulcers, nodules or vesicles	Common	Common
Neurological	May present with CNS disease or peripheral nervous system involvement	Mononeuritis multiplex occurs in 10–50%	Mononeuritis multiplex in > 50%
Chest Imaging	Abnormal chest imaging findings are very common (> 80%); may present with alveolar, interstitial or mixed infiltrates, or nodular or cavitary disease	Pulmonary infiltrates occur in 10–30%	Pulmonary infiltrates are common (40– 75%); may also see changes consistent with asthma (*e.g.* airway wall thickening and hyperinflation)
ANCA	ANCA-positive in >90% and c-ANCA/anti-PR3 ELISA positive in >85% with generalized active disease	ANCA-positive in 50–75% with most of these being p-ANCA/anti-MPO positive	ANCA positive in 45–70% with most of these being p-ANCA /anti-MPO positive

probability of disease), a positive C-ANCA/ anti-PR3 has sufficient PPV that biopsy may be deferred. False-positive ANCA test results have been reported. Particularly, subacute bacterial endocarditis has been reported with positive C-ANCA/PR3.[14] The clinical utility of the serial measurements of ANCA levels in follow-up is less well established. Although there is an association between ANCA titers and disease activity, if the only finding is the elevation of ANCA levels, this does not always predict disease relapse, but requires close follow-up of the patient with clinical and laboratory exams.[15]

Bronchoscopy

This study is helpful in the evaluation of alveolar hemorrhage, infection, airway disease, and endobronchial lesions. Transbronchial biopsy specimens are usually insufficient to diagnose vasculitis. Bronchoscopy may also be used as needed for palliative measures for narrowed airways (i.e. stents balloon dilatation).[10]

Diagnosis

Diagnosis needs tissue specimen for both WG and MPA. This can be achieved for WG disease by taking tissue from upper respiratory tract (URT), skin lesions or kidney, since transbronchial lung biopsy (TBLB) is of limited value. However, if the patient presents with the typical involvement of URT, renal and AH or pulmonary cavitating nodules and c-ANCA/PR3 positive, the diagnosis can be safely made.

Differential Diagnosis

Various forms of vasculitis (MPA, Goodpasture's syndrome, etc.) may lead to pulmonary hemorrhage or pulmonary-renal syndrome, similar to Wegener granulomatosis.

Pulmonary infarcts, septic pulmonary emboli, metastatic squamous cell carcinoma, fungal infection, rheumatoid nodules and lymphomatoid granulomatosis should be considered when the presentation includes multiple solid and cavitating nodules. In the presence of disease as consolidation with fever and hemoptysis differentiation should include infectious pneumonia, organizing pneumonia (OP) or eosinophilic pneumonia (EP) or drug toxicity. History, failure to respond to antibiotic treatment, transbronchial BAL and TBLB and more importantly the presence of significant drop of hematocrit and glomerular erythrocytes in the urine may provide the correct diagnosis.

The differential diagnosis of ENT manifestations includes sinus infection, cocaine abuse, sarcoidosis, primary NK/T-cell lymphoma/nasal type, etc., and tracheal stenosis differentiation includes postintubation stricture or trauma, relapsing polychondritis, sarcoidosis, inflammatory bowel disease, and amyloidosis.

Although the list of differential diagnoses and other problems is exceedingly broad and varied, the differential diagnosis can usually be limited by evaluating the radiographic findings in the context of the clinical history, simple laboratory exams (Hematocrit, hypoxemia, urinalysis) and the presence of PR3-ANCA**.**

Microscopic polyangiitis (MPA): MPA is a necrotizing systemic vasculitis with few or no immune deposits that affects small vessels (i.e. capillaries, venules or arterioles) and in contrast to WG there is no granulomatous formation. Since the discovery of ANCA, MPA has been differentiated from PAN. In addition to differences in the size of the vessels involved, lung involvement is rare in polyarteritis nodosa.

MPA more frequently affects men and the median age of onset is 50 years. Clinically, renal involvement, predominantly rapid progressive glomerulonephritis (RPGN), is a major feature of MPA, which is essentially universal. Most patients have systemic symptoms. Pulmonary involvement is seen in upto 30% of patients.[16] DAH with capillaritis pathology is the most common pulmonary manifestation.[17] Fleeting focal infiltrates to massive lung hemorrhage and hemoptysis can occur and is an important contributory factor to morbidity and mortality.[18] Ground-glass attenuation, consolidation, thickening of the bronchovascular bundles, nodular lung lesions, honeycombing, pulmonary interstitial fibrosis, obstructive lung disease, and pulmonary artery aneurysms have been observed in some patients with MP.[19-21]

Joint, skin, peripheral nervous system and gastro-intestinal (GI) involvement are also relatively common (Table 124.3). The vasculitis of MPA is indistinguishable from that of WG, and there may be a substantial clinical and ANCA overlap.

A positive P-ANCA is seen in 50 to 75% of patients, and anti-MPO is seen in 35 to 65% of patients, whereas a positive C-ANCA can be seen in 10 to 15% of patients. Histologically, a focal, segmental necrotizing vasculitis and a mixed inflammatory infiltrate without granulomata are seen.

Management of WG and MPA

The management of WG and MPA currently follows the same basic principles.

For treatment stratification, the disease activity is categorized as limited or severe. "Severe disease" is either life-threatening or threatening organs with irreversible loss of function and includes the following manifestations of the disease: Alveolar hemorrhage, glomerulonephritis, nervous system involvement including sensory-neural hearing loss and eye involvement (except mere episcleritis). Most of these manifestations are caused by capillaritis. All the other patients are thought to have limited disease and the symptoms in this case are the result of necrotizing granulomatous inflammation. Similarly, the European Vasculitis Study Group (EUVAS) recommends grading disease severity of the AAVs into the following five categories:[4]

- Localized: Upper and/or lower respiratory tract disease without any other systemic involvement or constitutional symptoms
- Early systemic: Any, without organ-threatening or life-threatening disease
- Generalized: Renal or other organ-threatening disease, serum creatinine level less than 5.6 mg/dL
- Severe: Renal or other vital-organ failure, serum creatinine level exceeding 5.6 mg/dL
- Refractory: Progressive disease unresponsive to glucocorticosteroids and cyclophosphamide.

Current standard therapy of ANCA- associated vasculitides (WG and MPA) is based on disease severity. The aim of the treatment is to control disease activity with minimal exposure to the toxicity of the drugs necessary to achieve this goal. The standard therapy for limited disease consists of the combination of oral glucocorticosteroids with methotrexate (MTX) 25 mg once a week, which is noninferior and has fewer side effects compared to cyclophosphamide (CYC).[22] In the largest reported group of patients with limited Wegener (WGET) >90% of patients achieved remission with this regimen and > 70% achieved sustained remission more than 6 months.[23]

The standard treatment for patients with severe WG or MPA is CYC at a dose of 2 mg/kg/day orally in combination with glucocorticosteroids. Glucocorticoids are usually given orally, but, if a rapid response is needed, such as in the case of RPGN and/or AH, intravenous pulse methylprednisolone (0.5-1 g/d for three consecutive days) can be used. Initial high-dose glucocorticoids (0.6-1 mg/kg/d) should be continued for atleast one month, tapered by 5 mg per week to 10 mg/day. Doses should not be reduced to less than 15 mg/d within the first three months. The dose should then be slowly tapered to a maintenance dose of 10 mg/d or less during remission. Consensus now is to limit the duration of CYC therapy to the first 3–6 months.[4] Once remission has been induced, CYC should be switched to either azathioprine (AZA) or MTX. AZA is preferred in patients with renal involvement and any degree of renal insufficiency. Mycophenolate mofetil (MMF) represents another alternative for AZA or MTX for remission maintenance. However, MMF is much more expensive and there are not many randomized trials comparing the effectiveness of the different remission maintenance agents.[24]

Whenever CYC is used for remission induction, consideration should be given to the patient's fertility. When a patient has persistent disease activity on maximal tolerated dose of CYC or has contradictions for the use of CYC then he is thought to have ***refractory disease***. The above mentioned treatment for severe disease is repeated when there is a severe flare.

Alternative newer therapies that could be used are:

Mycophenolate mofetil (MMF) is a derivative of the fungus *Penicillium stoloniferum* that, similar to azathioprine that limits purine synthesis. MMF may be considered in patients with MPO-ANCA-associated MPA and mild renal disease for remission induction in severe disease.

The addition of **plasma exchange therapy (PLEX)** to the standard cyclophosphamide - corticosteroid regimen has been shown beneficial to patients with rapidly progressive disease.[25]

B-cell depletion with **Rituximab (RTX),** a monoclonal anti-CD20 antibody that targets a subset of B-lymphocytes is currently used for patients with refractory disease. It may become a more widely used alternative to CYC, since it is considered a less toxic treatment, if the hypothesis of the RAVE trial is proven. In a recent series of 11 patients with active ANCA-associated remission was induced in all 11 patients, and ANCA titers became undetectable in eight patients.[26,27]

Anti-TNF therapy for AAV has been disappointing, and there is currently no role for these agents in AAV.[23] There are several reports on the use of other agents, such as antithymoglobulin, but toxicity limits their use.

Invasive bronchoscopy techniques or even surgery can be considered in the case of bronchial or subglottic stenosis, fibrotic changes deformities of the nose.

Follow-up

Patients with Wegener's granulomatosis (WG) should have regularly scheduled follow-up visits. Since recurrences occur frequently, patients should be monitored closely clinically, with radiological studies and laboratory examinations: CBC, serum creatinine levels, urinalysis, ESR, C-reactive protein, PR3-ANCA levels. All of the above exams, except ANCA, should be repeated in every two weeks.

Toxicity of the therapy should always be investigated. Infection due to treatment-related immunosuppression is a major contributor to morbidity and mortality in WG. Sometimes it is difficult to differentiate infection from disease flare. The physician should have a low threshold for treating suspicious symptoms with antibiotics. Prophylaxis against *Pneumocystis* pneumonia is essential while patients are receiving conventional therapy for WG (CYC-high doses of CS). TMP-SMX single-strength daily or double-strength formulation three times per week should be administered. Dapsone 100 mg daily can be used in sulfa-allergic patients.

All patients who require long-term glucocorticosteroid treatment are at risk for glucocorticosteroid-induced osteoporosis. Baseline bone mineral density should be evaluated. If the density is normal, patients should take daily calcium and vitamin D supplementation. If diminished at baseline or if long-term glucocorticosteroid use is anticipated, bisphosphonate therapy should be added.

Mesna should be administered to prevent hemorrhagic cystitis, which is a frequent complication of CYC and urine cytology should be performed in every six months as the potential long-term complication of CYC is the carcinoma of the bladder.

Churg-Strauss syndrome (CSS): According to the Chapel Hill Consensus Conference, a patient fulfills the definition for CSS if: asthma, peripheral eosinophilia, eosinophilic-rich granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small- to-medium-sized vessels are found. As mentioned previously, CSS is one of the three ANCA-associated vasculitides, where in more than half of the patients with active CSS, ANCA are detected. In 75% of these patients, the ANCA pattern is p/MPO positive, while 25% present with c-ANCA pattern.[28,29] CSS is the rarest of the three, with the incidence rates of definite CSS among asthma patients ranging from 0 to 67 per million person every year. Apart from the rarity of the syndrome, the fact that its various clinical manifestations rarely coincide makes CSS diagnosis a challenge for the clinician.

Disease usually develops in stages. The first (prodromal) stage is characterized by asthma, which is the disease predominant feature, with or without allergic rhinitis and nasal polyps. The second stage consists of peripheral blood eosinophilia (>10%) and eosinophilic tissue infiltration. The last phase is the most severe and consists of systemic vasculitis. Each of these stages can last for years and they do not always follow each other; any of them can be missed. However, asthma usually precedes vasculitis by a mean of seven years and usually is refractory to standard asthma treatment. The differential diagnosis is based on the predominant symptom, which can be different in each phase. If the symptoms are focused on respiratory system, other pulmonary eosinophilic syndromes, such as parasitic infections, drug reactions, acute and chronic eosinophilic pneumonia, allergic bronchopulmonary aspergillosis and hypereosinophilic syndrome should be excluded, before CYC is induced in addition to steroids.

Respiratory tract involvement is common. The major pulmonary symptoms are related to asthma, which is present in all patients. In addition, radiographic imaging studies reveal transient peripheral alveolar-type infiltrates, present in >70% of the cases. Nodular lesions or eosinophilic pleural effusion can be seen occasionally. DAH is extremely rare, in contrast to WG and MPA. Peripheral nervous system involvement in the form of mononeuritis or polyneuritis multiplex, skin, heart, central nervous system and gastrointestinal system may also be involved. Renal involvement is less common than in WG and MPA and is usually mild. **(Table 124.3).** Laboratory findings include peripheral blood eosinophilia on complete blood count, elevation of serum IgE and markers of inflammation (C-reactive protein and erythrocyte sedimentation rate). As mentioned before in 40 to 70% of the patients, ANCA are detected, 75% of which are p-ANCA reacting with myeloperoxidase and 25% c-ANCA. The ANCA status appears to correlate with disease activity. Diagnosis needs histological specimen from peripheral nerve or lung and compatible clinical and serological findings.

There has been much discussion about possible pathogenic link between leukotriene receptor antagonist (montelukast, zafirlukast) and the onset of CSS. There is no evidence suggesting that these agents cause CSS, but that they allow dose reduction or discontinuation of oral corticosteroid in asthmatic patients, a fact that may lead to unmasking of CSS.

Patients with CSS respond very well to high dose systemic glucocorticosteroids. In patients with life-threatening manifestations of the disease, that is nervous system involvement, glomerulonephritis, heart involvement or DAH, cyclophosphamide should be added to glucocorticosteroids. Finally, other less toxic immunosuppressive drugs (methotrexate, azathioprine, etc.) could be used for remission maintenance. RTX has also been successfully used in CSS.[30]

Other Causes of Vasculitis Involving the Lungs

Systemic Lupus Erythematosus (SLE) and Other Collagen Vascular Disorders: DAH due to pulmonary capillaritis with prominent immune complex deposits in SLE is a rare, but life-threatening complication. Joint symptoms usually precede and patient is already diagnosed as having SLE; therefore diagnosing the cause of hemoptysis in such patient—provided that infectious pneumonia is excluded, is usually easy by finding high presence of siderophages in BAL and glomerular erythrocytes in urine.[31] Some anecdotal reports refer that hemoptysis may be presenting before any other involvement occurs and then the diagnosis may be delayed or missed. Almost always the onset is abrupt with pulmonary infiltrates, fever and hemoptysis. The latter may be absent in 50% making the differential diagnosis between infection and DAH difficult and diagnostic BAL is usually required. High mortality rates have been reported with AH in SLE.[32] Treatment consists of glucocorticosteroids and cyclophosphamide. PLEX has been suggested, but there is not enough data to prove its benefit yet.

A small vessel vasculitis (pulmonary capillaritis) has been reported in several patients with polymyositis, rheumatoid arthritis and mixed connective tissue disease.[33,34]

Giant Cell Arteritis: Giant cell arteritis (GCA) also called temporal arteritis, cranial arteritis and granulomatous arteritis is the most common primary vasculitis that affects large- and medium-sized vessels.[35] The incidence of GCA increases with age and is often associated with polymyalgia rheumatica. The most typical features of the disease include new-onset severe headache, a palpably tender or nodular temporal artery, visual symptoms, that is amaurosis fugax and visual loss. The gradual development of nonspecific systemic symptoms, such as low-grade fever, malaise and weight loss and an elevation of erythrocyte sedimentation rate (ESR) are common. Pulmonary complications, reported up to 25% of patients include cough, sore throat and hoarseness. Other abnormalities described in isolated cases include interstitial or nodular pulmonary lesions, pleural effusion, pulmonary infarction, lymphocytic alveolitis and aneurysms of the pulmonary artery. Therapy consists of corticosteroids, that usually lead to the resolution of pulmonary symptoms.

Takayasu's Arteritis: Takayasu's arteritis (TA) is chronic inflammatory vasculitis characterized by stenosis, occlusion and sometimes aneurysms of the large arteries, mainly the aorta and its main branches, including coronary and renal arteries.[36] TA is found predominantly in the Asia, Middle East and South Africa, although the disease has been described in Western population. The female/male ratio is 8.5:1 and the majority of patients are between 11 and 30 years of age. Early disease manifestations include constitutional symptoms, fever, weight loss and arthralgias. After weeks or months, vascular lesions appear and ischemic disease of the involved vessels develops. Variable pulses of the upper and lower extremities and intermittent claudication of the affected vascular territories are typical. Aortic insufficiency, renovascular hypertension and ischemia of the affected organs may be some complications of the progressive and relapsing disease.

Significant number of patients with TA have pulmonary artery involvement (approximately 50%). Pathology is similar to aorta and includes defects of the outer media of the arteries, ingrowth of granulation tissue-like capillaries, thickened fibrosed intima, transmular inflammation, lymphoplasmatic infiltrations with a variable amount of giant cells and subendothelial muscle proliferation. These morphological changes in pulmonary arterial wall, lead to pulmonary artery stenoses and occlusion and the development of pulmonary hypertension. Pulmonary symptoms include chest pain and hemoptysis, although they are not very often. Chest roentgenograms are not very helpful in detecting pulmonary involvement as they are usually normal. Conventional angiography, perfusion scan, computed tomography and magnetic resonance angiography usually provide valuable information.

Therapy of TA consists of glucocorticosteroids. Other immunosuppressive agent, such as methotrexate could be used for remission induction and as corticosteroid-sparing agents for remission maintenance. Unfortunately, relapses are often when the dose of corticosteroids is reduced to less than 10 mg/d. Surgery may be needed in patients with significant vascular disease.

Behçet Disease: Behçet disease (BD) is a chronic relapsing systemic inflammatory disorder characterized by aphthous oral ulcers along with two or more of the following: aphthous genital ulcers, uveitis, synovitis, cutaneous nodules or pustules, or meningoencephalitis. Most of the reported cases are from countries around the Mediterranean basin and Japan and the usual onset is in the third decade. Most studies have reported a predominance of men with disease over women. There is a strong association with the major histocompatibility complex antigen HLA-B5. Respiratory symptoms are not rare (about 10% of patients) and include hemoptysis, which can be massive, cough, chest pain and dyspnea. The vasculitis in BD may affect both arteries and veins, so that arterial aneurysms and major venous occlusion can occur accordingly. Aspirin and not anticoagulation has been advocated for thrombosis prevention. The most serious complications are pulmonary arteries aneurysms, erosion of the bronchial wall and arterial- bronchial wall fistulae that almost always are associated with hemoptysis, often fatal. Other manifestations of the diseases include lung infiltrates, recurrent pneumonias and bronchial occlusion. Fever, elevated ESR and anemia are common.[37]

Evaluation of thoracic involvement in BD, apart from chest radiographs, should include CT or MRI angiographs.

Immunosuppression with the combination of prednisone with another drug, such as colchicines, methotrexate, azathioprine or cyclosporine is recommended and may result in the resolution of pulmonary aneurysms. Anticoagulation should be avoided in case of arteritis. Prognosis is poor in patients with pulmonary involvement, since 30% die within 2 years due to fatal pulmonary hemorrhage.

Goodpasture's syndrome: Goodpasture's syndrome, also known as anti-basement membrane antibody disease (ABMA) is an extremely rare (one case per 1,000,000 population per year) autoimmune disorder, characterized by the presence of autoantibodies against the NC1-domain of the a3 chain of the glomerular basement membrane and, less commonly, the alveolar basement membranes.[38] This binding of antibodies, which is a cytotoxic (type II) reaction can be visualized as the linear deposition of immunoglobulin by direct immunofluorescent techniques and anti-GBM antibody can be found in the serum in >90% of the cases.

The disease predominantly affects Caucasians of any age, but mostly those in the second to third decades and the fifth to sixth decades of life, with a slight predominance in males. The cause of Goodpasture's syndrome is unknown, but influenza virus, hydrocarbon exposure or penicillamine and unknown genetic factors are known to stimulate anti-GBM antibody production.

Clinically the most common manifestations consist of DAH and RPGN with anti-GBM antibodies. These occur in 60 to 80% of patients with manifestations of pulmonary and renal disease, 20 to 40% with renal disease alone, and fewer than 10% have disease that is limited to the lungs.[39] DAH occurs in about half of the patients with ABMA and almost always precedes renal manifestations. An additional inhalation injury, particularly smoking, is required for the development of pulmonary manifestations of the disease. Active cigarette smoking increases the risk of DAH. In about 30% of the patients, p-ANCA-mpo positive are detected and AH is more likely to develop in those patients.

The most frequent histopathological feature of DAH is bland hemorrhage, without vasculitis, although some combined findings with vasculitis have been reported.

Immunosuppressive therapy in conjunction with PLEX is the treatment of choice in ABMA. The pulmonary outcome of ABMA is generally favorable, whereas chronic renal failure is common.[40]

Polyarteritis Nodosa: Polyarteritis nodosa (PAN) is characterized by necrotizing lesions affecting predominantly small- to-medium-sized muscular arteries.[41] PAN has been separated from microscopic polyangiitis and does not affect capillaries. Therefore, it does not cause alveolar hemorrhage or glomerulonephritis. Pulmonary involvement is very rare in patients with PAN. Anecdotal reports of cases of medium-sized bronchial and pulmonary arteries involvement in patients with PAN have been described. An association with hepatitis-B virus has been documented in a minority of patients diagnosed with PAN. Immunosuppression with antiviral agents is treatment of choice in such cases. Recurrences of the disease and ANCA are rare in PAN, in contrast to microscopic polyangiitis.

Infection

Among the primary vasculitides, those that affect the small vessels, Wegener's Granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis, are grouped together as the **ANCA-associated vasculitides.** The vasculitides associated with pathologic **granulomata** include Wegener's granulomatosis, Churg-Strauss syndrome, Takayasu's arteritis and giant cell arteritis.

Pulmonary Hypertension: A Third World Prospective

Zeenat Safdar

INTRODUCTION

Pulmonary Hypertension (PH) is characterized by an increase in mean pulmonary artery pressure that may lead to right ventricular failure and premature death.[1] The pathophysiology of PH is complex and incompletely understood; however, the pathologic changes appear in part from an imbalance between mediators of vasodilatation (e.g. prostacyclin, Nitric Oxide [NO]) and vasoconstriction (e.g. Endothelin-1) in favor of the vasoconstrictive forces, and promotion of vascular smooth muscle cell proliferation in the small pulmonary arteries.

Pulmonary hypertension is defined hemodynamically by the presence of elevated mean Pulmonary Artery Pressure (PAP) of equal to or greater than 25 mm Hg.[2,3] The term primary pulmonary hypertension has been abandoned instead pulmonary hypertension is divided into five diagnostic groups as outlined in Table 125.1. The treatments discussed below are indicated for the Diagnostic Group I and their use in other diagnostic Groups is not recommended.

Pulmonary Arterial Hypertension [(PAH) Diagnostic Group I] is defined by a mean PAP $\geq$ 25 mm Hg with a Pulmonary Capillary Wedge (PCWP) or LVEDP of less than or equal to 15 mm Hg.[2,3] These criteria define PH associated with multiple other disease processes, including Chronic Obstructive Pulmonary Disease (COPD)[4] (Table 125.2). On the other hand, Pulmonary Venous Hypertension [(PVH) Diagnostic Group II] is defined by a mean PAP $\geq$ 25 mm Hg with a Pulmonary Capillary Wedge (PCWP) or LVEDP of more than or equal to 15 mm Hg (Table 125.2). These definition were used by the National Institute of Health Registry to define Primary Pulmonary Hypertension in the 1980's and recently revised at the 4th World Symposium on Pulmonary Hypertension.[5]

Prior to the availability of specific therapies, PAH (Diagnostic Group I) was considered a rapidly fatal illness with a median survival of 2.8 years.[2] Advances in the treatment have positively influenced prognosis and survival of these patients.[2,3] The revised PH classification proposed at the 3rd World Conference on Pulmonary Hypertension in Venice 2003 replaced the Evian classification of PH from 1998.[6] The major difference was the abandonment of the term primary pulmonary hypertension and classifying PAH as idiopathic, familial and associated with other conditions.[6] Recent revision of PH classification undertaken at the 4th World Symposium on Pulmonary Hypertension includes among other changes replacement of the term familial with heritable pulmonary arterial hypertension (Table 125.1).

Pulmonary hypertension and right ventricular enlargement occurring secondarily to chronic lung or chest wall disease, recognized as chronic cor pulmonale has been long considered as an independent disease, especially in the developing countries. The problem continues to pose a challenge in differential diagnosis and management of PH. Chronic cor pulmonale is a syndromic diagnosis, which occurs as a long-term complication of an underlying lung/chest wall or pulmonary vascular disease. It also encompasses the disorders of respiratory regulation and chronic central hypoventilation with hypoxemia and carbon dioxide retention. Pathophysiologically, the end result is the development of pulmonary hypertension that may lead to right ventricular failure.

TABLE 125.1: Updated Classification of Pulmonary Hypertension (Dana Point 2008)

Group I: Pulmonary Arterial Hypertension (PAH)

- Idiopathic PAH
- Heritable – BMPR2, Alk1, unknown
- Drug- and toxin-induced
- PAH assoicated with
  - Collagen vascular disease
  - Congenital heart disease
  - HIV
  - Schistosomiasis
  - Portal hypertension
  - Chronic hemolytic anemia
- Persistent pulmonary hypertension of newborn
- Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis

Group II: Pulmonary Hypertension due to left heart disease

- Systolic dysfunction
- Diastolic dysfunction
- Valvular disease

Group III: Pulmonary hypertension owing to lung disease and/or hypoxemia

- Chronic Obstructive Pulmonary Disease (COPD)
- Interstitial lung disease
- Other pulmonary disease with mixed restrictive and obstructive pattern
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Developmental abnormalities

Group IV: Chronic Thromboembolic Pulmonary Hypertension (CTEPH)

Group V: Pulmonary hypertension with unclear multifactorial mechanisms

- Hematological disorders: Myeloproliferative disorders, splenectomy
- Systemic disorders: Sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
- Metabolic disorders: Glycogen stroage disease, Gaucher disease, thyroid disorders
- Others: Tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

CLINICAL FEATURES

Presenting symptoms of PH are nonspecific; include fatigue, dyspnea, worsening exercise limitation, sporadic chest pains, abdominal distention and pedal edema. With progression of disease, the right ventricle starts to fail and cardiac output falls. This phase may manifest with worsening symptoms progressing to presyncope or even syncope.[7] As this process progresses unabated, it may lead to right heart failure, shock and death.

TABLE 125.2: Hemodynamic Classification of Pulmonary Hypertension

Pulmonary hypertension	*Mean PAP ≥ 25 mm Hg*	*All groups*
Precapillary pulmonary hypertension	Mean PAP ≥ 25 mm Hg PCWP ≤ 15 mm Hg Cardiac output normal or reduced	Group I – PAH Group III – PH due to lung disease Group IV – CTED Group V – PH multi-factorial etiology
Postcapillary pulmonary hypertension	Mean PAP ≥ 25 mm Hg PCWP > 15 mm Hg Cardiac output normal or reduced/increased	Group II – PH due to left heart disease

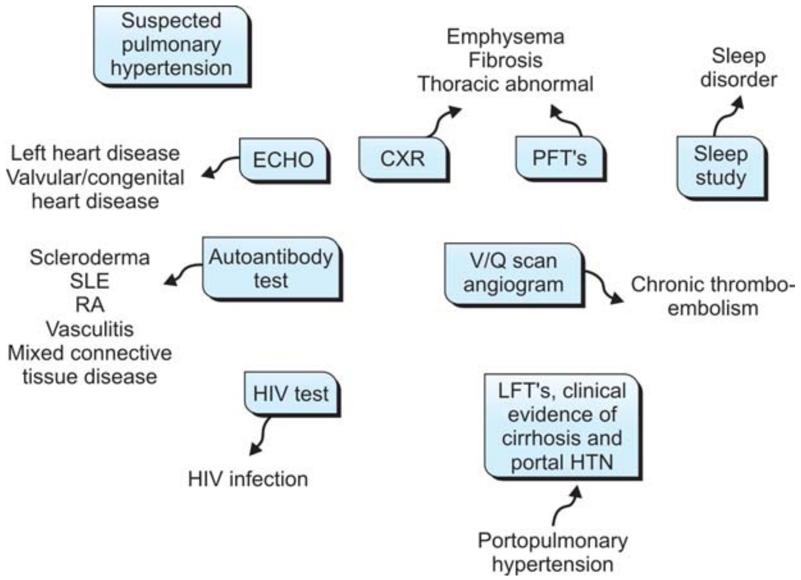
Physical examination: Physical findings will depend upon whether patient is in a compensated or a decompensated cardiovascular state. In early compensated phase, physical examination may be nonspecific. Accentuated second heart sound (P2) may be heard indicating elevated PAP. Presence of midsystolic murmur caused by turbulent flow across the pulmonary artery, left parasternal heave, right-sided S4 gallop and prominent jugular "a wave may be seen".[7] As disease progresses, hepatojugular reflex and inspiratory augmented tricuspid murmur (Caravallo's sign) may become apparent. Signs of right heart failure include pulsatile liver, marked distention of jugular veins, ascites and peripheral edema develop.[8] Cold extremities and systemic hypotension may be present when cardiovascular collapse ensures.

Signs of chronic lung disease, such as those of emphysema, interstitial lung disease (ILD) or chest wall abnormalities (e.g. kyphoscoliosis) are present in cases of chronic cor pulmonale.

Stigmata of Collagen Vascular Disease (CVD) can provide clues to the presence of CVD associated PH. These include skin changes of scleroderma (skin thickening/tightening, nail fold changes, telangiectasias), butterfly rash of lupus, heliotrope rash of dermatomyositis/polymyositis. The incidence of PAH is higher in patients with mixed connective tissue disease and reported as high as 38%.[9] Human Immunodeficiency Virus (HIV) infection has been associated with an increase prevalence of PAH up to 0.5%.[10]

DIAGNOSTIC EVALUATION

Diagnostic evaluation is aimed at two components: A) Diagnosis of the presence and severity of pulmonary hypertension and B) Etiological diagnosis. Pulmonary



Suspected pulmonary hypertension
Emphysema
Fibrosis
Thoracic abnormal
Sleep disorder
Left heart disease
Valvular/congenital heart disease
ECHO
CXR
PFT's
Sleep study
Scleroderma
SLE
RA
Vasculitis
Mixed connective tissue disease
Autoantibody test
V/Q scan angiogram
Chronic thrombo-embolism
HIV test
HIV infection
LFT's, clinical evidence of cirrhosis and portal HTN
Portopulmonary hypertension

Fig. 125.1: Evaluation of pulmonary hypertension

hypertension occurring as a complication of chronic lung, chest wall, cardiac or collagen vascular disorders is discussed in individual chapters.

A number of diagnostic tests are required to be undertaken when PH is suspected in a new patient (Fig. 125.1). Suspicion for pulmonary hypertension, based on the history and physical examination, necessitates an echocardiogram that is a useful screening tool (Table 125.3). However, right heart catheterization is required to confirm the diagnosis.

Electrocardiogram (ECG): Electrocardiogram is a poor screening tool to diagnose pulmonary hypertension. Suggestive ECG findings include right-axis deviation; RSR pattern in lead V1, tall R wave and small S wave with R/S ratio > 1 in lead V1, qR complex in lead V1, large S wave and small R wave with R/S ratio < 1 in lead V5 or V6; or S1, S2, S3 pattern. ST-T segment wave depression and inversion may be present in the right precordial leads. Right atrial enlargement manifests as a tall P wave (>2.5 mm) in leads II, III, and aVF and frontal P-axis of 75°.[7]

Chest Radiography (CXR): CXR may reveal the following suggestive findings: Enlarged main and hilar pulmonary arterial shadows with attenuated peripheral pulmonary vascular markings (pruning), right ventricular enlargement seen on the lateral films as impingement of the anteriorly situated right ventricular silhouette into the retrosternal clear space.[8] Chest Radiography will also show the evidence of emphysema, other lung parenchymal diseases or chest wall deformity in case of chronic cor pulmonale.

TABLE 125.3: Pulmonary Hypertension Work-up

PH suspicion	Symptoms, history and physical examination
PH screening test	Echocardiogram
PH confirmation	Right heart catheterization
PH classification	Group I – Pulmonary arterial hypertension Group II – PH due to left heart disease Group III – PH due to lung disease Group IV – CTED Group V – PH multifactorial etiology
PH severity	6MWD Echocardiographic assessments NYHA/WHO FC

Echocardiogram (ECHO): This is a commonly used screening tool for evaluating pulmonary hypertension (Table 125.3). It is a simple, noninvasive test that can provide detail assessment of biventricular function and anatomy. Doppler ECHO can be used to calculate the Right Ventricle Systolic Pressure (RVSP) in the presence of tricuspid regurgitation jet. Presence of tricuspid jet is crucial to this measurement.

Pulmonary artery pressure approximately equals to right ventricular systolic pressure in the absence of pulmonary artery outflow obstruction or stenosis. The RVSP is approximated by the modified Bernoulli equation as $4v^2$, in which v is the velocity of the tricuspid jet in meters per second. Right Ventricle Systolic Pressure is obtained by adding right atrial pressure (RAP) to the RVSP.[7] Right Atrial Pressure estimate is based on either the height of jugular venous pulse or echocardiographic features of inferior vena cava.

$$\text{RVSP} = 4v^2 + \text{RAP}$$

Fisher et al. compared echocardiographic estimate of PAP with right heart catheterization, ECHO was performed within one hour of the RHC, and PAP was inaccurate (> 10 mm Hg variability) in 48% of cases.[11] Overestimation and underestimation were noted and the magnitude of underestimation was considered more prominent. This study elucidates the inadequacy of ECHO in both identifying and quantifying PAP.[11]

Ventilation-Perfusion Scan: This is an important test to determine the presence of chronic thromboembolic disease (CTEPH). Chronic thromboembolic disease is a potentially curable by patients undergoing pulmonary endarterectomy. In various studies, $\dot{V}/\dot{Q}$ scan has shown a sensitivity of 90 to 100% and specificity of 94 to 100% in differentiating between patients with idiopathic PAH and CTEPH. $\dot{V}/\dot{Q}$ scan is also useful to look for the presence of an underlying lung disease that will be evident as ventilation defects.

Computerized tomography of the chest: This is an emerging diagnostic modality in pulmonary hypertension. Advances in CT technology have led to improved imaging of heart and pulmonary vasculature. In one study, main PA diameter of 3.32 cm had 58% sensitivity and 95% specificity for the presence of PAH.[12] However, mean PAP used in this study was lower than the accepted definition of PH. Multidetector-row CT with three-dimensional volume rendering can elucidate pulmonary vein anatomy in the thorax. Abnormalities in the pulmonary venous drainage can prompt evaluation for structural anomalies causing PH.[13] Contracter et al. evaluated the role of helical CT chest in diagnosing right ventricule (RV) dysfunction after acute pulmonary embolism. Right ventricular dilation and deviation of interventricular septum towards left ventricle (LV) were the criteria used to define RV dysfunction. The sensitivity of CT chest for detecting RV dysfunction was 78% and specificity 100%, with a positive predictive value of 100%.[14]

Computed tomography chest is of particular help to diagnose a chronic lung disease, such as the bronchiectasis, COPD or interstitial lung disease.

Pulmonary function tests: Isolated reduction in the diffusion capacity of the lung for carbon monoxide (DLCO) is strongly suggestive of pulmonary vascular disease. In the absence of other lung pathology, isolated reduction in DLCO may be the only abnormal finding in lung function testing. Spirometry is particularly useful to assess the presence of severity of airflow obstruction.

Serological evaluation: A complete serological evaluation should be undertaken early in patients with PAH (as noted above). This should include testing for serological markers of systemic lupus erythematous, scleroderma, rheumatoid arthritis, polymyositis/dermatomyositis and mixed connective tissue diseases. Up to 40% of patients with PAH may have elevated antinuclear antibodies.[15]

Right heart catheterization (RHC): This remains the gold standard to diagnose of pulmonary hypertension. Right heart catheterization provides accurate measurement of mean PAP, right atrial pressure and cardiac output, and pulmonary capillary wedge pressure to determine the presence of pulmonary arterial vs. pulmonary venous hypertension.[7] Pulmonary vascular reactivity is assessed during catheterization and presence of reactivity has important therapeutic and prognostic implications in the treatment of PAH.[16]

Agents commonly used for vasoreactivity testing are inhaled nitric oxide, adenosine and intravenous epoprostenol. The definition of a positive vasodilator response is reduction of mean PAP equal to or more than 10 mm Hg and absolute reduction in the mean PAP to less than 40 mm Hg.[16] Unfortunately, less than 10% of patients elicit a positive vasodilator response and only 50% of initial responders remain responsive on repeated vasodilator testing.[17] Patients with a positive vasodilator response exhibit a better prognosis when treated with long-term calcium channel blocker therapy.[16]

Six-minute walk test: Exercise capacity in a PH patient is assessed by a six-minute walk test. It is a nonencouraged walk test that is conducted according to American Thoracic Society guidelines.[18] Several studies have demonstrated the prognostic ability of a six-minute walk distance (6MWD), which was the primary end point in several randomized clinical trials that led to the FDA approval of these drugs to treat PAH in USA. In a study by Miyamoto, PAH patients that walked < 332 meters had worse survival than patients who walked further. In addition, the distance walked significantly decreased in proportion to the severity of New York Heart functional class.[19]

World Health Organization/New York Heart Association (WHO/NYHA FC) Functional Class: It is determined at every clinic visit in PAH patients as outlined in Table 125.4 and has prognostic implication. Untreated patients who were in FC III or IV status had worse prognosis as compared to patients in FC I or II [2]. Goal of therapy is to improve FC. Patients that were treated with epoprostenol and remained in FC III or IV after three months of therapy had a 33% probability of survival over three years whereas patients in FC I or II had 88% probability of survival over three years.[20]

TABLE 125.4: World Health Organization/NYHA Classification of Functional Status in Pulmonary Hypertension Patients

Class	Description
I	Patients with PH in whom there is no limitation of usual physical activity; physical activity does not cause increased dyspnea, fatigue, chest pain or presyncope.
II	Patients with PH who have mild limitation of usual physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain or presyncope.
III	Patients with PH who have marked limitation of usual physical activity. There is no discomfort at rest, but less than ordinary activity causes increased dyspnea, fatigue, chest pain or presyncope.
IV	Patients with PH who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest and symptoms are increased by almost any physical activity.

PATHOPHYSIOLOGY

Under normal conditions, pulmonary vasculature is a low resistance, high flow and high capacitance system. In pulmonary hypertension, pulmonary vasculature resistance (PVR) increases, leading to resistance to the flow of blood through the pulmonary vasculature. This may exhibit as RV strain and when the RV cannot overcome the increased resistance, right heart failure ensures.

The pathophysiology of PAH in Diagnostic Group I has been studied in much greater detail than in other diagnostic groups II to IV. However, similar pathology may exist in these groups also. PAH involves pulmonary arteries of less 500 µm. It is characterized by intimal proliferation, medial hypertrophy and adventitial hyperplasia. The muscularization of the small pulmonary arteries leads to decreased vascular lumen. Endothelial dysfunction has a main role in PH. There is increased production of endothelin-1, the most potent vasoconstrictor known to mankind, in the diseased pulmonary vasculature. In addition, there is increased production of vasoconstrictor thromboxane and decreased production of vasodilator, such as prostacyclin and nitric oxide (NO), which is recognized as an important endothelium derived vasodilator playing a major role in maintaining vascular tone in normoxemic pulmonary vasculature.[21] Increased shear may contribute to the increase in vascular tone in the presence of reduced NO production.[22] In addition to excessive vasoconstriction, both endothelin and thromboxane has vascular remodeling effects that lead to muscularized pulmonary arterioles.

In addition to medial hypertrophy, and intimal fibrosis, pulmonary hypertension is associated with thrombi *in situ* in small muscular pulmonary arteries.[1] The increased platelet aggregation may be due to abnormal arachidonic acid metabolism as shown by an elevated urinary metabolite of thromboxane (TXA_2) and reduced urinary metabolite of protacyclin (PIG_2) in pulmonary hypertension.[23,24]

MANAGEMENT

Treatment of the etiological cause constitutes the cornerstone of management of PH associated with chronic lung or heart diseases. The objectives of treatment of chronic cor pulmonale, for example consist of management of hypoxemia and airway obstruction. Pulmonary arterial pressures will fall with satisfactory management of the underlying etiology. The role of pulmonary pressure lowering drugs is neither established nor recommended in PH associated with left heart failure, lung disease or chronic thromboembolic disease (Diagnostic Group II-V).

Avoidance of Airway Irritants

Tobacco smoke is the most common cause of COPD. Multiple studies have reported improvement in functional markers, symptoms, morbidity and mortality in COPD with smoking cessation. Smoking cessation is an integral part of COPD management. All smokers irrespective of symptoms should be counseled on the deleterious effects of smoking and cessation strategies implemented.

Oxygen Therapy

Hypoxic vasoconstriction plays an important role in the pathophysiology of pulmonary hypertension. Oxygen therapy is a cornerstone in management of hypoxemia in these patients. Two seminal trials documented survival benefit with long-term oxygen therapy in COPD. Nocturnal Oxygen Treatment Trial (NOTT) included subjects with arterial PaO_2 55 mm Hg or less or arterial PaO_2 59 mm Hg or less with coexisting peripheral edema, hematocrit at least 55% or pulmonale. This trial demonstrated a survival benefit of continuous supplemental oxygen therapy over nocturnal oxygen use, and the average duration of treatment was 19.3 months. Pulmonary vascular resistance and hematocrit reduced more in subjects that were on continuous oxygen therapy.[25] The Medical Research Council (MRC) trial included patients with severe COPD, PaO_2 between 40 and 60 mmHg, hypercapnia and history of congestive heart failure.[26] Subjects received either oxygen for at least 15 hours per day, usually at 2 L per minute or no oxygen. A survival benefit with the use of continuous oxygen was noted after 500 days. In this study, subjects on room air showed increase PAP whereas subjects on oxygen therapy showed no such increase.

Anticoagulation

In situ thrombosis is a part of the pathology of pulmonary hypertension.[27] Improved survival has been demonstrated in patients with idiopathic pulmonary arterial hypertension who were treated with oral anticoagulation.[28] Therefore, anticoagulation is recommended in idiopathic PAH patients with no contraindication for anticoagulation.

Diuretics

In the presence of signs of right heart failure (peripheral edema, ascites, hepatomegaly) use of diuretics is strongly encouraged. Patients should be advised to maintain near-normal intravascular volume and monitor salt and water intake. Diuretics commonly used are furosemide (loop diuretic) and spironolactone (aldosterone receptor antagonist). Aggressive diuresis should be avoided to prevent systemic hypotension, acute renal failure and hemodynamic compromise.

Digoxin

Digoxin has not been extensively studied in PAH. Digoxin acts by decreasing the function of Na^+/K^+ ATPase pump in the myocardium, thereby increasing the myocardial contractibility. It also increases Central Nervous System (CNS)- mediated vagus activity thus decreasing AV nodal conduction. Digoxin may be useful in refractory right heart failure to augment RV function and increase cardiac output in PAH.[23]

Vasodilator Therapy

Multiple pharmacological agents modulate vascular remodeling in addition to their pulmonary vasodilatory effects. Several drugs are now available to treat PAH associated with Group I diseases. Three major pathways [endothelin pathway, prostacyclin pathway and nitric oxide pathway] have been implicated in the pathogenesis of PAH. Eight drugs targeting these pathways are currently Food and Drug Administration (FDA) approved to treat PAH (Diagnostic Group I classification) in United States. These include epoprostenol,[4] treprostinil,[5] inhaled treprostinil,[24] iloprost,[6] bosentan,[7] ambrisentan,[8] sildenafil and tadalafil.[22,9] Studies in PAH have shown the effectiveness of these agents on pulmonary hemodynamics, however, these are not indicated to treat pulmonary hypertension related to left heart disease, lung disease or chronic thromboembolic disease. More studies are needed before the available PAH medication can be recommended for use for these indications.

Endothelin Pathway: Endothelin-1, a peptide produced in endothelial cells and vascular smooth muscle cells, binds and activates 2 G protein–coupled receptors, ET_A and ET_B. ET_A is located predominantly on smooth muscle cells, whereas ET_B is found on both endothelial and vascular smooth muscle cells.[1,29-31] Activation of the ET_A receptor on smooth muscle cells causes sustained vasoconstriction and proliferation of these cells. However, activation of ET_B on endothelial cells induces clearance of endothelin-1 from the circulation and mediates vasodilation through the activation of NO and prostacyclin. Endothelin-1 is over expressed in PAH and is thought to be important in the pathogenesis of the disease. [12] Therefore, antagonists to endothelin receptors were developed as targeted PAH therapeutic agents.

Endothelin receptor antagonists: Bosentan was the first ERA to be available to treat PAH. It is considered a nonselective competitive antagonist of ET_A and ET_B receptors and ambrisentan is referred to as an ET_A-selective antagonist. Bosentan and ambrisentan have a relative affinity for ET_A over ET_B of 20:1 and 77:1, respectively based on in vitro competitive receptor binding assay.[32-34] According to one theory, ambrisentan should selectively block vasoconstrictive effects of ET_A

while maintaining vasodilatory and endothelin-1–clearing properties of the ET_B receptor. Despite an apparent receptor selectivity advantage for ambrisentan, a clinically meaningful difference in efficacy between agents has not been demonstrated.[31] Hence, factors, such as adverse events and drug interactions may be more relevant when considering treatment with an ERA agent.

Phosphodiesterases: Phosphodiesterases are a super family of enzymes that inactivate cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate, the second messengers of NO and prostacyclin, respectively.[1] Production of NO is impaired in patients with PAH,[35] resulting in decreased production of cGMP. One advancement in PAH therapy was to prolong the circulation of existing cGMP by inhibiting its inactivation by phosphodiesterases. PDE-5 is the predominant and selective phosphodiesterase in the pulmonary tissue.[36] PDE-5 inhibitors increase cellular cGMP levels causing preferential pulmonary vasodilation with less significant reductions in systemic blood pressure.

Phosphodiesterase 5 inhibitors: Sildenafil and tadalafil are PDE-5 inhibitors that have similar mechanisms of action.[37] Both sildenafil and tadalafil have higher selectivity for PDE-5 than for PDE-1, PDE-2, PDE-3 and PDE-4, at a level of 80- to >1000-fold for sildenafil and >10,000-fold for tadalafil. Currently, approved therapies for the treatment of PAH function through different pathways. These pathways are not distinct and are thought to interact with one another in a complex manner that has yet to be fully elucidated. Prostacyclin and NO are also known to reduce the release of endothelin-1, thus controlling the signaling for endothelin receptors.[29] Together these complex interactions promote aberrant cellular growth, vasoconstriction and thrombosis within the pulmonary arteries.

Prostanoids: Endogenous prostacyclins, produced by endothelial cells of blood vessels, are decreased in patients with PAH.[38,39] There are 4 prostanoid receptors in the lung that are considered to be involved in regulating vascular tone, platelet activation, and immunological cell responses.[40] Hence, prostanoids (prostacyclins and prostacyclin analogues) are a rational choice for the treatment of this disease. Current guidelines recommend the use of prostanoids in patients with PAH functional class II-IV.[41] In addition, sequential combination therapy with prostacyclin analogs, PDE5-i and ERA's should be considered if adequate response with monotherapy is not achieved or if patients deteriorate with monotherapy;[41] however, data supporting the use of combination therapy are limited and these therapies are the focus of current research.[42]

Prostanoids Agonist

Prostanoids have been used in routine clinical practice in PAH patients since the 1990s, although their investigational use was reported in 1980s.[43,44] Currently, there are several different prostanoids available in different formulations [for intravenous (IV) use, as a subcutaneous (SC) injection, and for inhalation].[45]

Epoprostenol: Epoprostenol, also known as synthetic prostaglandin I_2, was the first therapy approved in 1995 by the United States (US) FDA for the treatment of PAH.[46,47] Derived from the metabolism of arachidonic acid, it is a potent pulmonary and systemic vasodilator, an inhibitor of platelet aggregation,[47,48] and may modulate pulmonary vascular remodeling.[49]

The systemic half-life ($t_{1/2}$) of epoprostenol is 2 to 3 minutes. Epoprostenol metabolism in humans results in 2 major metabolites, which are primarily excreted via the kidneys.[48,50-52]

Clinical studies in PAH patients demonstrated improvement in hemodynamic parameters, functional status and exercise capacity (6-minute walk distance [6MWD]) with epoprostenol treatment.[48,51,53-59] Dose-dependent decreases in several parameters were observed with IV epoprostenol therapy, including total pulmonary resistance, pulmonary vascular resistance (PVR) and mPAP, and increases in cardiac index and stroke volume.[48,51,55] The hemodynamic effect of epoprostenol is similar in the acute and chronic settings.[48,51,52] Intravenous epoprostenol improved survival and the only PAH medication to have an indication for survival in its prescribing information.[48,50,55] However, in patients with scleroderma associated pulmonary hypertension, no significant improvement in survival was observed with epoprostenol therapy relative to conventional therapy.[54]

Treprostinil: Treprostinil is a synthetic prostanoid that is stable at room temperature and has a neutral pH.[60,61] Similar to epoprostenol, treprostinil is a potent pulmonary and systemic vasodilator, and an inhibitor of platelet aggregation.[60-62] Parenteral treprostinil is available as a branded product only (Remodulin®; United Therapeutics Corp.).[61] The manufacturer recommends that treprostinil be administered via a continuous SC infusion, with IV infusion used only in the event of intolerance to SC administration (e.g. severe injection site pain/reactions).[61]

Treprostinil is metabolized by the liver into five metabolites, which are primarily excreted in the urine. Treatment of patients with PAH with IV or SC treprostinil improves hemodynamic parameters and exercise capacity.[63-68] The effects of treprostinil on hemodynamics have been variable.[63,65-68] In a study comparing IV treprostinil with epoprostenol, the hemodynamic changes were similar for both of these agents.[65] Bioequivalence of IV and SC treprostinil was shown in a study in healthy volunteers.[69] In animal studies, the use of treprostinil reduced ventricular afterload (both right and left) and increased stroke volume and cardiac output.[61]

Iloprost: Iloprost is a synthetic prostaglandin I_2 analogue. Like epoprostenol and treprostinil, iloprost is a systemic and pulmonary vasodilator that also has antiplatelet properties.[70] Iloprost is available as a mixture of the 4S and 4R stereoisomers; with respect to vasodilation, the 4S isomer is more potent than the 4R isomer.[71] Iloprost is marketed under the brand name Ventavis® (Actelion Pharmaceuticals US, Inc.) in the US.[71] The systemic $t_{1/2}$ of inhaled iloprost is 20 to 30 minutes; Iloprost is metabolized via oxidation to produce one major metabolite, which is primarily excreted in the urine.[71]

Inhaled iloprost improves hemodynamic parameters, functional status and exercise capacity.[72-79] In addition, iloprost added to stable ongoing bosentan therapy significantly delayed the time to clinical worsening.[80] Hemodynamic effects of iloprost in humans include decreases in PVR and mPAP and increases in cardiac output and oxygen saturation after 12 weeks and 2 years of treatment.[75,79] Unlike the parenteral prostanoids, the effect of inhaled iloprost on mean systemic arterial pressure has been variable; some studies show no effect,[78,81-83] whereas others see significant reduction.[75] It has also been shown that patients receiving inhaled iloprost do not experience rebound symptoms during the night, which may occur with interruption of parenteral infusion of epoprostenol or treprostinil.[84]

Inhaled Treprostinil: The inhaled formulation of treprostinil is the most recent prostacyclin to be approved by the US FDA (July 2009). It is marketed under the brand name Tyvaso™ by United Therapeutics.

Systemic exposure of inhaled treprostinil was found to be proportional to the administered dose in a single-dose study in healthy volunteers;[85] in one study, including patients with PAH, 30 mcg/dose (4x/day) and 45 mcg/dose (4x/day) caused a maximum blood concentration of 0.33 ng/mL and 0.96 ng/mL, respectively, time to maximum concentration was 15 minutes and 45 minutes, respectively, and $t_{1/2}$ was 44 to 52 minutes.[86] Similar dose-proportionality in patients with PAH was reported in a second study.[87] Hemodynamic effects of inhaled treprostinil included decreases in mPAP and PVR.[86,87]

Clinical studies of inhaled treprostinil have been conducted in patients already receiving the endothelin receptor antagonist bosentan or the phosphodiesterase type-5 inhibitor sildenafil, and have shown that inhaled treprostinil significantly improved hemodynamics, functional class, and exercise capacity when added to oral therapy.[85-87] However, in one study (TRIUMPH-I), inhaled treprostinil when added to oral therapy significantly improved exercise capacity (6MWD) and did not improve the functional class.[86]

Oral Prostanoids

Oral formulations of prostanoids and one prostacyclin agonist are currently in development. An oral formulation of treprostinil has been developed by United Therapeutics; however, this formulation has not yet been approved in the US and is currently undergoing assessment in clinical trials.[45,88-90] Similarly, the prostacyclin analog beraprost has launched in Japan and Korea by Kaken Pharmaceuticals and is also undergoing assessment in the US.[91-102] In addition, there is a long-acting nonprostanoid prostacyclin receptor agonist prodrug, ACT-293987 (also known as NS-304), in the development for treatment of PAH by Actelion Pharmaceuticals.[103,104]

SUMMARY

Pulmonary Hypertension is a serious disease that carries a high mortality. Although echocardiogram is a good screening tool, a right heart catheterization is required to confirm this diagnose. Correct diagnosis is important as treatment options will depend upon these results. The currently available therapies are indicated to treat patients in PAH (Diagnostic Group I). Use of these agents to treat pulmonary hypertension in other Diagnostic Group [Diagnostic Group II-IV] is not recommended.

Pulmonary Thromboembolism

Devasahayam J Christopher, Richa Gupta

INTRODUCTION

Pulmonary thromboembolism (PTE) commonly called pulmonary embolism (PE) and deep vein thrombosis (DVT) are different manifestations of the same disease. PE is a disorder that holds the interest of a wide variety of medical practitioners, including the general physicians, pulmonologists, cardiologists, surgeons, obstetricians, radiologists, nuclear physicians, pathologists and others. For long, despite an improved understanding of the pathogenesis and consequently the use of preventive measures, morbidity and mortality from PE remained unchanged. The recent advances in the diagnostic strategies, pharmacotherapeutics and surgical management have decreased mortality from venous thromboembolic disease significantly in the past few decades.[1] Although there have been technological advances in management, for most clinicians in the third world countries, like India, the tests such as ventilation-perfusion lung scanning and spiral CT are not readily available.

EPIDEMIOLOGY

In most cases, PE is a consequence of DVT, of whom about 50% have an associated, usually clinically asymptomatic PE at lung scan.[2] In about 70% of patients with PE, DVT can be found in the lower limbs, if sensitive diagnostic methods are used.[3, 4] Although DVT and PE are manifestations of a single disease, PE has features that are distinct from DVT. The risk of death related to the initial acute episode or to recurrent PE is greater in patients who present with PE than in those who present with DVT.[5] According to prospective cohort studies, the acute case fatality rate for PE ranges from 7 to 11%.[6] Also, recurrent episodes are about three times more likely to be PE after an initial PE than after an initial DVT (60% vs 20%).[6] The overall age and sex-adjusted annual incidence of venous-thromboembolic disease is approximately 1 to 2 cases per 1000 persons and is considered strongly age dependant as the incidence rises to about 1% per year in persons greater than 75 years of age.[7, 8]

A recent epidemiological study confirmed that venous thromboembolism (VTE) is a major public health burden with an estimated 370,000 related deaths in 2004 in six European countries.[9] Moreover, PE may lead to chronic thromboembolic pulmonary hypertension, which can be severely disabling.[10, 11] PE has been shown by autopsy studies to be the cause of mortality in 10% of all hospital deaths, and contributing to mortality in a further 10%. Two thirds of the cases were unsuspected and unconfirmed antemortem. Furthermore, it is well known that only one third of cases suspected as PE on the basis of clinical symptoms are confirmed by investigations to be so (Fig. 126.1).

PATHOPHYSIOLOGY

The pathophysiology of PE includes the formation of DVT and subsequent embolization into the pulmonary arteries. Current evidence confirms that the factors related to clot formation, i.e. venous stasis, increased blood coagulability and injury to the vein wall (Virchow's triad) are the most important factors in the pathogenesis of VTE. The most common source of pulmonary emboli

RV infarction, RV failure

Fig. 126.2: Pathophysiology and cardiovascular consequences of PE

is thrombosis in the deep veins of the lower limbs, particularly between the knee and the inguinal ligament. PE is infrequently due to thrombosis of the pelvic veins, veins of the upper extremities or other organ systems (e.g. hepatic and renal veins). The thrombus dislodges and travels through the venous circulation and lodges in one of the pulmonary arteries. The embolism results initially in an area of the lung that is ventilated but under perfused, resulting in an alveolar dead space. Release of vasoactive substances, like serotonin from the platelets and the blockade of the pulmonary artery by the clot, cause an elevation of pulmonary vascular resistance. This results in an increase in right ventricular workload, leading to a redistribution of blood flow and increase in right ventricular workload which, if excessive, may result in right ventricular failure (Fig. 126.2). Once this occurs there is a fall in the pulmonary blood flow and reduction of left ventricular filling, causing systemic hypotension.

Airway obstruction resulting from the reflex bronchoconstriction further contributes to the ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. After about 24 hours, there is depletion of surfactant which may result in atelectasis and edema of the affected area. Pulmonary infarction itself is an uncommon consequence of PE, because the pulmonary parenchyma has three potential sources of oxygen, namely—the pulmonary arteries, the bronchial arteries and the alveoli. Generally, two of these sources need to be compromised before infarction develops and this usually happens only in patients with coexisting cardiopulmonary disease. Also, complete occlusion of the pulmonary artery is infrequent. Although the site of the clot and the extent of obstruction determine the severity of the disease and the outcome, in the presence of pre-existing cardiopulmonary disease, a small embolic event in the pulmonary artery may result in serious consequences. Conversely, a major occlusion in one of the main pulmonary arteries may have lesser consequences in a person with a normal pre-existing cardiopulmonary status.

RISK FACTORS

Venous thromboembolism is currently considered to be the result of an interaction between patient-related and setting-related risk factors.[12] Patient-related predisposing factors are usually permanent; whereas setting-related risk factors are more often temporary (Table 126.1). However, the predictive values of these factors are not equal and VTE can occur in patients without any identifiable predisposing factors.

Surgery and Fractures

Recent surgery and fractures, particularly of the femur and tibia, pose an increased risk. In surgical patients, the high risk groups are those that have major high-risk operations performed for abdominal or pelvic malignancy, major orthopedic surgery and any surgery requiring intensive care. The likely causative factors are immobility and liberation of clotting factors.

Malignancy

Although the exact mechanism is unknown, abnormalities of homeostasis occur in patients with neoplastic disease. A well known example is the association of thrombophlebitis migrans with

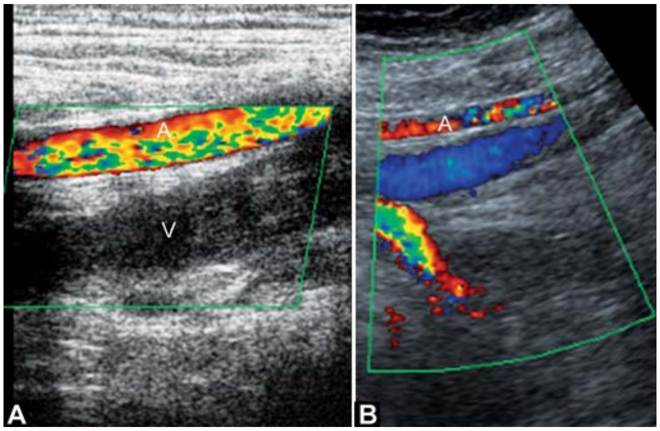
TABLE 126.1: Risk factors for pulmonary thromboembolism

Major risk factors		*Minor risk factors*
Surgery and bone fractures	• Abdominal/pelvic surgery • Hip/knee replacement • Postop ICU care • Bone fractures especially of tibia and femur	• Oral contraceptive use • Hormone replacement therapy • Myocardial infarction • Congestive cardiac failure • Congenital heart disease • Superficial venous thrombosis • Indwelling central vein catheter • Chronic obstructive airway disease • Increasing age • Occult malignancy • Thrombotic disorders • Long distance sedentary travel • Obesity
Malignancy	• Pancreatic • Bronchial • Genitourinary • Stomach and colon • Breast • Advanced/metastatic	
Obstetrics	• Pregnancy (late) • Peurperium • Cesarian section	
Immobilization (especially lower limb)	• Plaster of Paris cast • Paralysis • Hospitalization • Institutional care	
Others	Previous proven VTE	

gastrointestinal tract malignant disease. The association of venous thromboembolism is seen most often with pancreatic cancer, followed in the order of frequency by carcinomas of the bronchial tree, genitourinary tract, colon, stomach and breast. In one series, cancer was found to be a risk factor in 22.3% of the patients with venous thromboembolism.

Pregnancy and Puerperium

Venous thromboembolism is one of the leading causes of maternal morbidity and mortality. About two thirds of these cases occur during pregnancy and one third during postpartum. A recent case-control study showed that the risk of VTE was increased fivefold (OR 4.6, 95% CI 2.7–7.8) during pregnancy and 60-fold (OR 60.1, 95% CI 26.5–135.9) during the first 3 months following delivery compared to non-pregnant females.[13] The risk was highest in the third trimester of pregnancy and during the first 6 weeks after delivery. In pregnancy and puerperium, the clot formation is probably due to venous stasis in the lower limbs resulting from decreased venous return due to direct pressure from the enlarged uterus. Increased levels of some of the clotting factors and possible reduction in fibrinolytic activity may also contribute. In pregnancy, Doppler ultrasound (Figs 126.3A and B) can help to diagnose deep vein thrombosis.



Figs 126.3A and B: Color doppler images of the external iliac artery (A) and external iliac vein (V) in a patient with DVT (image A) and in a patient with patent veins (image B). In 'image A', thrombosed external iliac vein (V) is dilated and shows echogenic intraluminal thrombus, without color uptake. In 'image B'; the patent vein (V) shows normal color uptake

Immobilization

Immobilization for more than a week is an important risk factor. Diminished muscle activity in the lower limbs reduces venous return, facilitating accumulation of activated clotting factors.

Oral Contraceptive Therapy

Most Oral Contraceptives (OCP) consist of a combination of oestrogen and progestogen. The reduction in dose of oestrogen has been reduced over time; this has reduced the risk of VTE in females. However, there is still a twofold to fivefold increased risk, with the risk being highest during first year of use.[14]

Cardiorespiratory Disorders

The source of the emboli in these diseases is also the veins of the lower limbs, rather than the heart itself. In these situations, the risk of clot formation in the leg veins is probably enhanced by the reduction in the peripheral blood flow. Venous thromboembolism has been reported to be over three times more common in patients with heart disease (aged 30 years or more) than in age matched controls.

Inherited Causes

Deficiencies of natural coagulation inhibitors, such as antithrombin, protein C and protein S, are strong risk factors for VTE, but these deficiencies are rare and account for only 1% of all cases of VTE. Factor V Leiden and prothrombin (factor II) G20210A mutations are two more common genetic variants that have been consistently found to be associated with VTE, but still explain only a small proportion of VTE cases.

Age

Age is an important risk factor. In one series, 88.5% of the patients diagnosed with PE were aged 40 years or more.

CLINICAL FEATURES

The clinical presentation of PE can vary widely from one patient to another. Evaluating the likelihood of PE in an individual patient according to the clinical presentation is of utmost importance, not only for the interpretation of the diagnostic test results but also for the selection of an appropriate diagnostic strategy.[15] In 90% of cases, suspicion of PE are raised by clinical symptoms, such as dyspnea, chest pain and syncope, either alone or in combination (Table 126.2). In several series, dyspnea, tachypnoea or chest pain were present in more than 90% of patients with PE.[16, 18]

The initial presentation usually falls into one of the following three categories:[17]

TABLE 126.2: Prevalence of symptoms and signs in patients with PE[18-20]

Symptoms	*% of patients*
Dyspnea	80
Chest pain (pleuritic)	52
Chest pain (sub-sternal)	12
Cough	37
Leg pain	26
Syncope	19
Hemoptysis	11
Signs	*% of patients*
Tachypnea	70
Tachycardia	26
Loud P2	23
Signs of DVT	15
Cyanosis	11
Fever	7

1. *Pulmonary infarction syndrome*: The patients who fall in this category present with dyspnea and pleuritic chest pain. The severity of PE is deemed to be mild. This is the most common mode of initial presentation. In one study, three-quarter of the patients presented this way.
2. *Isolated dyspnea*: In these patients, the only symptom is acute shortness of breath. These patients are often hypoxic, and PE in these patients is deemed to be moderate. This presentation is encountered in roughly one-fifth of the patients.
3. *Circulatory collapse*: Patients in this category present with circulatory collapse, characterized by shock or syncope. PE in these people is deemed to be severe.

It is good to keep the following factors in mind during clinical assessment of a patient with suspected PE:
- Pleuritic chest pain, with or without dyspnea, is one of the most frequent presentations of PE. Moderate-to-large embolism may be associated with retrosternal; angina-like chest pain, which may reflect right ventricular ischemia.
- The onset of dyspnea may at times be insidious in onset and progressive over several weeks, the diagnosis of PE is considered by the absence of other causes of dyspnea.
- Syncope, a rare presentation of PE, may indicate a severely reduced hemodynamic reserve.

On physical examination, tachypnea is the most common sign. Other signs include—tachycardia, crackles, fever, diaphoresis, cyanosis, parasternal heave, loud pulmonary component of the second heart sound, third or fourth heart sound, wheezes, pleural friction rub, hepatomegaly and hepatojugular reflux. These findings are common to several cardiopulmonary disorders and so have low specificity. Since lower limb DVT is the cause of PE in the majority of cases, it is prudent to look for local pain, tenderness, redness and warmth. Unfortunately, these signs are also non-specific and may even be misleading at times.

DIAGNOSIS

The diagnosis of PE requires the integration of a careful history and physical examination with laboratory testing and appropriate imaging modalities.

Routine Investigations

A chest radiograph is usually the first investigation ordered for patients presenting with symptoms of PE, followed by ECG. Routine investigations, like chest X-ray, ECG and 2D-ECHO, are of limited value in the diagnosis of PE. More importantly, they contribute in excluding many common conditions with similar clinical presentation like; acute myocardial infarction, acute aortic dissection, pneumonia, pneumothorax, cardiac failure. Chest radiographic abnormalities are common in patients with PE; but they are not diagnostic (Table 126.3). Abnormal electrocardiogram may be seen in patients with PE, quite frequently, but the ECG abnormalities are also not specific for PE (Table 126.4).

D-dimer Testing

D-dimers are formed as a result of fibrin degradation and rise with intravascular coagulation. The levels in plasma reflect the fibrinolytic activity on pre-existing thrombi; and not necessarily the rate of thrombus formation. D-dimer levels are non-specific, which can be elevated in various conditions like cancer, inflammation, peripheral vascular disease, in hospitalized patients including obstetrics.[21, 22]

D-dimer levels have low specificity and positive predictive value;[23] elevated D-dimers cannot be used for the confirmation of diagnosis of PE,[15] nor a normal D-dimer test be used to overrule the clinical judgment of a physician in suspecting and performing further investigations for PE in patients with high clinical probability. However, the test has a high negative predictive value and reliably excludes PE in patients with low or intermediate clinical probability.[12]

TABLE 126.3: Radiological signs of PE[17]

Common	*Rare*
• Atelectasis	• Focal oligemia (*Westermark's sign*)
• Raised hemidiaphragm	• Wedge shaped density above the diaphragm (*Hampton's sign*)
• Focal infiltrate	• Enlarged right descending pulmonary artery (*Palla's sign*)
• Small pleural effusion	• Cardiomegaly

TABLE 126.4: Electrocardiographic findings in PE

Electrocardiography
• Sinus tachycardia
• T wave inversion in leads V1-4
• S1Q3T3 pattern
• New RBBB

Deep Venous Thrombosis Testing

Compression ultrasonography (CUS) is used as an indirect method for diagnosing PE. CUS has a sensitivity of over 90% for proximal DVT and a specificity of about 95%.[24, 25] It shows DVT in 30 to 50% of patients with PE[24, 25] finding a proximal DVT in patients suspected of PE is sufficient to warrant anticoagulant treatment without further testing.[15] The only validated diagnostic criterion for DVT is incomplete compressibility of the vein, which indicates the presence of a clot, whereas flow criteria are unreliable.[15] Proximal CUS can be performed and, when positive in patients with contraindications to contrast, CT can be avoided.[15]

Radioisotope Ventilation-Perfusion Scan ($\dot{V}/\dot{Q}$ Scan)

Ventilation-perfusion scintigraphy ($\dot{V}/\dot{Q}$ scan) is a well established diagnostic test for suspected PE (Fig. 126.4). It is non-invasive and safe to apply barring a few allergic reactions that have been described. The ventilation and perfusion phases of a $\dot{V}/\dot{Q}$ lung scan are performed together. A chest X-ray would be useful to have comparison and to look for other causes of lung disease. A defect in the perfusion images requires a mismatch in the ventilation scan, implying normal ventilation in the corresponding area, to be deemed as suggestive of PE. In the ventilation phase of the test, a gaseous radionuclide xenon, ^{133}Xe or Tc-99 m-labeled aerosols or Tc-99 m-labeled carbon microparticles (Technegas) is used. The perfusion phase of the test involves the intravenous

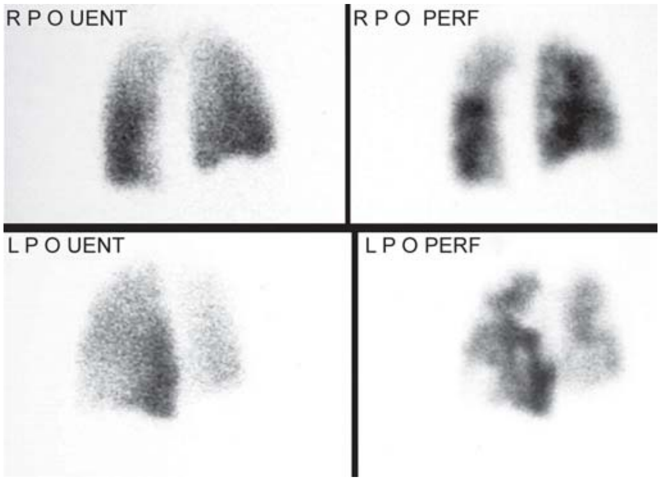


Fig. 126.4: Ventilation-perfusion lung scan shows a number of unmatched ventilation-perfusion defects; consistent with pulmonary thromboembolism

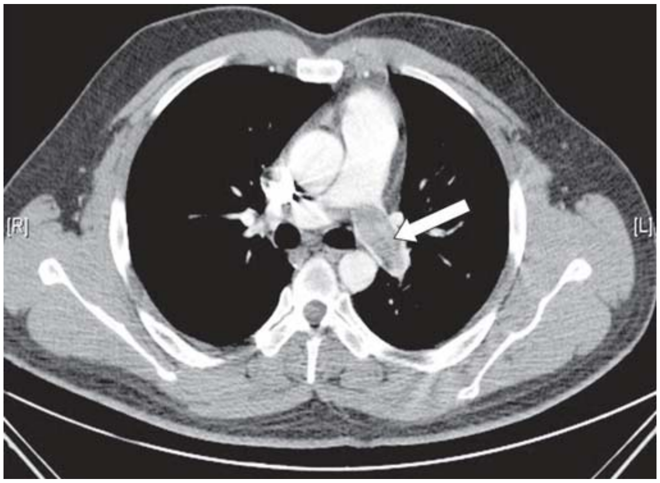

Fig. 126.5: CT-PA showing filling defect (arrow) in the main pulmonary artery at the origin of the left main pulmonary artery, suggesting thromboembolism

injection of radioactive technetium macroaggregated albumin (Tc99m-MAA), which blocks a small fraction of pulmonary capillaries and thereby enables scintigraphic assessment of lung perfusion at the tissue level. Where there is occlusion of pulmonary arterial branches, the peripheral capillary bed will not receive particles, rendering the area 'cold' on subsequent images.

Diagnostic accuracy of the $\dot{V}/\dot{Q}$ scan is greatest when the test is combined with clinical probability.[26] The value of the test could be summarized as follows:

- Patients with high clinical probability of PE and a high-probability $\dot{V}/\dot{Q}$ scan had a 95% likelihood of having PE.
- Patients with low clinical probability of PE and a low-probability $\dot{V}/\dot{Q}$ scan had only a 4% likelihood of having PE.
- A normal $\dot{V}/\dot{Q}$ scan virtually excludes PE.

In patients whose reports do not fall in the above categories, other confirmatory tests need to be done. $\dot{V}/\dot{Q}$ scan involved little risk for most people. The amount of radiation used together for ventilation and perfusion are about the same as the amount a person is naturally exposed to in a 1 year period. Although rare, the radioisotopes may cause allergic reactions.

Computer Tomography Pulmonary Angiography

Computer tomography-pulmonary angiography (CT-PA) is being increasingly used as a diagnostic modality for patients with suspected PE. In the past few years, it has become the procedure of choice for diagnosing PE (Fig. 126.5). One of the most commonly cited benefits of CT-PA is its ability to detect alternative pulmonary abnormalities that may explain the patient's clinical presentation.[27, 28] With spiral CT, the location and the magnitude of the thrombus is demonstrated and both mediastinal and parenchymal structures are evaluated, which may provide important alternate or additional diagnoses.

The main impediment for spiral CT has been the limitations of this modality for the accurate detection of small peripheral emboli.[29-31] Early studies comparing conventional single slice spiral CT with selective pulmonary angiography demonstrated high accuracy of spiral CT for detecting PE from the main pulmonary artery to the segmental arterial level,[32, 33] but they also concluded that sub-segmental emboli may be missed. Limitations in view of the inability to make a reliable diagnosis of small peripheral emboli, with a reported miss rate of upto 30% with single-slice spiral CT, have prevented the unanimous embrace of spiral CT as the new standard of reference for imaging PE.[34]

Although the accuracy of conventional single-slice spiral CT for the detection of isolated peripheral emboli may be limited, encouraging data are accumulating on the high negative predictive value of a normal spiral CT study.[28, 35-44] According to these studies, patient outcome is not adversely affected if anticoagulation is withheld on the basis of a negative spiral CT study. The high negative predictive value of a normal spiral CT study compares very favorably with catheter pulmonary angiography,[45] approaches 98% regardless of whether underlying lung disease is present.[39, 40] The frequency of a subsequent clinical diagnosis of PE or DVT after a negative spiral CT pulmonary angiogram is low, and much lower than that after a negative or low-probability $\dot{V}/\dot{Q}$ scan.[35, 37] Thus, even a single slice spiral CT appears to be a reliable imaging tool for excluding clinically relevant PE.

Lingering concerns about the accuracy of spiral CT for PE detection can be largely overcome by the advent of multidetector-row spiral CT (MDCT). With improved diagnosis of small peripheral emboli, MDCT is emerging as a preferred modality for imaging patients with suspected acute PE (Fig. 126.6). According to the Prospective Investigation of pulmonary embolism diagnosis (PIOPED) II study,[46] the sensitivity of MDCT was 83% and the specificity 96%. Positive predictive values were 96% with a concordantly high or low probability on clinical assessment, 92% with an intermediate probability on clinical assessment. Thus, new generation MDCT is now a challenge to catheter pulmonary angiography, the gold standard for the accurate detection of PE.[34]

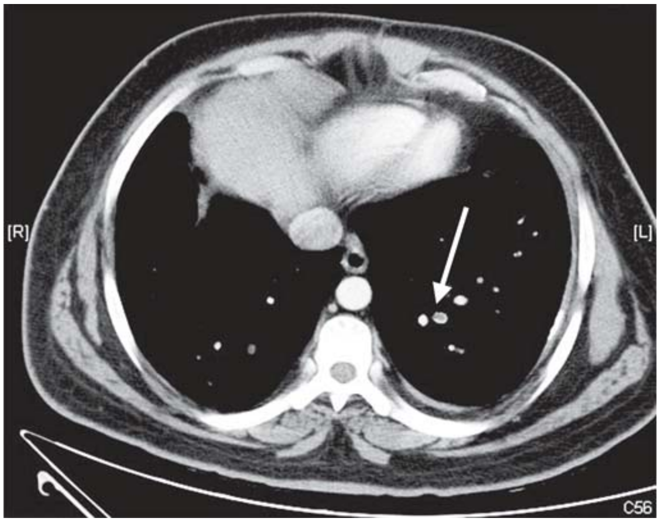

Fig. 126.6: Multidetector-Row Spiral CT (MDCT) showing filling defect (arrow) in a sub-segmental branches of the left descending pulmonary artery, suggesting thromboembolism

Pulmonary Angiography

Pulmonary angiography is still the gold standard investigation for the confirmation of PE (Fig. 126.7).[47] It is an invasive procedure with potential risks, therefore performed infrequently. It is indicated when cardiovascular collapse and hypotension are present, and when other investigations are inconclusive. The contrast is injected into the pulmonary artery via a catheter inserted through the femoral, internal jugular or the subclavian vein. The features indicating the presence of an embolus include intraluminal filling defect and abrupt vascular cut-off in pulmonary arteries. Fatal complications occur in 0.5 to 1.3% of the procedures and minor complications in 2% of patients.[17]

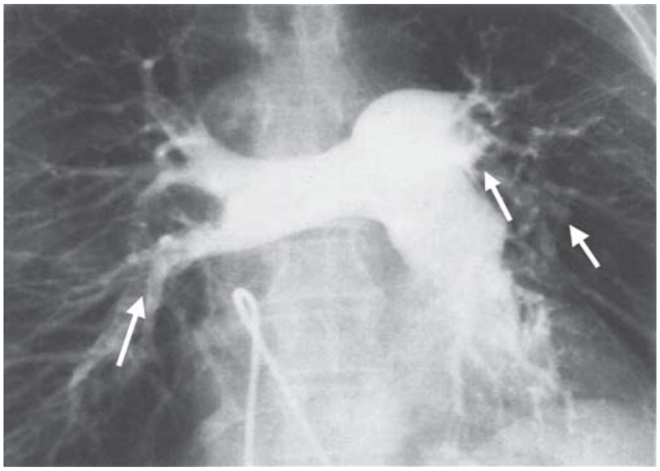

Fig. 126.7: Pulmonary angiogram showing several emboli obstructing pulmonary arteries (arrows)

CLINICAL PROBABILITY ASSESSMENT

In a patient with suspected PE, clinical probability assessment is considered as an essential step. The clinical pretest probability can be determined by taking into account the patient's clinical history, risk factors for VTE, clinical signs and the laboratory tests. The implicit evaluation of pretest probability was demonstrated to be relatively accurate in the PIOPED study.[48] Various clinical prediction rules are available for the diagnosis of PE, but the most widely used and validated in diagnostic studies are: (1) the Wells Score,[49] (Table 126.5) and (2) the Geneva Score.[50] The revised Geneva score proposed in 2006 (Table 126.6) is independent of the clinical judgement, chest radiographs and arterial blood gas analysis.[51]

Using one of the clinical prediction rules,[49, 51] the prevalence of confirmed PE is found to be 10% in low probability category, 30% in moderate category and 70% in high probability category.[52] Adopting one of these strategies may avert unnecessary investigations and may be cost saving. Therefore, we recommend its use in practice in resource limited settings like India. So far, these strategies have not been evaluated on clinical trials in developing countries.

TABLE 126.5: Wells score[49]

Variable		*Points*
Active cancer		+1
Hemoptysis		+1
Previous DVT or PE		+1.5
Heart rate > 100 beats/min		+1.5
Surgery or bed rest ≥ 3 days within 1 month		+1.5
Clinical signs of DVT		+3

Intermediate	4–10	22–31
High	≥ 11	58–82

DIAGNOSTIC STRATEGIES

Various combinations using clinical probability scores, D-dimer assays, lower limb imaging, ventilation perfusion lung scintigraphy and spiral CT have been evaluated in various studies to formulate diagnostic algorithms and for risk stratifications in patients with suspected PE. Recently, the European Society of Cardiology proposed diagnostic algorithms for patients with suspected high-risk (Fig. 126.8) and non-high-risk (Fig. 126.9) PE patients. Such algorithms need to be tailored to the needs of individual centers, based on the availability of investigative procedures and the resources.

TABLE 126.7: Features of right ventricular dysfunction

Echocardiography	• Rt Ventricular dilatation (without left heart disease) • Rt Ventricular free wall motion hypokinesia with sparing of apex (McConnell's sign) • Increased right ventricular after load • Pulmonary hypertension as tricuspid regurgitation with jet velocity > 2.8 m/sec
Right heart catheterization	• Impaired LV diastolic filling • Pulmonary arterial obstruction manifested as pre-capillary pressure > 20 mmHg and pulmonary capillary wedge pressure < 18 mmHg
Biomarkers	• BNP and pro-BNP

ASSESSMENT OF PROGNOSIS

Several strategies have been tried to prognosticate the out come in patients with PE. Some of them are as follows:

Clinical Assessment

Presence of hypotension and shock [defined as systolic blood pressure (SBP) less than 90 mm Hg or a drop of ≥ 40 mmHg for > 15 min] in patients with PE carries poor prognosis, and are the markers of high risk of death in acute PE.

Markers of Right Ventricular Dysfunction

Right ventricular dysfunction is related to intermediate risk of short-term mortality in acute PE. Echocardiographical findings suggesting right ventricular dysfunction have been reported to occur in at least 25% of PE patients.[53] More than a two fold increased risk of PE related mortality was found in patients with echocardiographic signs of right ventricular dysfunction.[54] Of various indices of right ventricular dysfunction (Table 126.7), there is lack of universally accepted criteria. However, a completely normal result should be considered as defining low risk PE. Right heart catheterization allows direct assessment of right ventricular filling pressures and cardiac output, but its routine use for risk stratification in acute PE is not recommended.

Ventricular dysfunction is associated with increased myocardial stretch which leads to the release of brain natriuretic peptide (BNP). Plasma BNP, released from myocytes of ventricles upon stretch, has been reported to differentiate pulmonary from cardiac dyspnoea. Different studies have shown that in acute PE, levels of BNP or N-terminal proBNP (NT-proBNP) reflect the severity of RVD and hemodynamic compromise.[55-58] BNP appeared to have better sensitivity and specificity than NT-proBNP in detecting right ventricular dysfunction.[59]

Although elevated BNP or NT-proBNP concentrations are related to worse outcome, their positive predictive value is low (12 to 26%).[15] On the other hand, low levels of BNP or NT-proBNP can be reliably used for identification of patients with a good prognosis regarding short-term mortality or a complicated clinical outcome (NPV 94 to 100%).[56, 60-64] A proBNP level less than 500 pg/ml was found to predict an uneventful hospital course in patients with acute PE.[65]

Markers of Myocardial Injury

Cardiac troponins T and I have both been reported to be elevated in acute PE in various observational studies. While right ventricular myocardium might not necessarily be its only source, elevated plasma troponin levels have been repeatedly reported as associated with worse prognosis in patients with PE.[66] It has also been observed that among patients with raised natriuretic peptide levels, increased serum troponins were associated with a further increase in the risk of adverse outcomes.[59] A cut-off value for troponin of greater than 0.09 ng/ml is a suitable predictor for death in hospital with a sensitivity, specificity, NPV and PPV of 80%, 92%, 99% and 34% respectively.[67]

New markers of myocardial injury are emerging; heart type fatty acid binding protein (H-FABP) is one of them. It is an early marker of myocardial injury, reported to be superior to troponin, NT-proBNP and myoglobin measurements for risk stratification of PE at admission. H-FABP greater than 6 ng/ml had a PPV and NPV for early PE-related mortality of 23 to 37% and 96 to 100% respectively.[68, 69] Growth Differentiation Factor (GDF-15) is another marker that has been found to be associated with complicated outcomes in patients with acute PE. The markers of myocardial injury, especially the newer ones, require further studies before they can be put to clinical use, establishing a role for the risk stratification of patients with PE.

MANAGEMENT

General Management

Analgesia should be given to patients with severe pleuritic pain, but opiates should be avoided in patients with incipient cardiovascular collapse since they cause vasodilatation. Hypoxemia should be treated with high percentage inspired oxygen, severe hypoxia may require ventilation. In hypotensive patients, colloids should be administered while monitoring central venous pressure; the right atrial pressure should be maintained high (15 to 20 mm Hg) to ensure maximal right ventricular filling. Use of ionotropic agents may be required to provide circulatory support. Diuretics and vasodilators are not indicated.[17]

Medical Treatment

Anticoagulation is the main stay of treatment for acute PE. The main objectives of anticoagulant therapy in the initial treatment of PE are to prevent thrombus extension while allowing endogenous fibrinolysis to proceed, and to prevent early and late recurrences of VTE. From the point of view of therapy patients suffering from PE can be classified into one of the following subsets:[70]

- *Stable PE:* Normotensive patients (when SBP ≥ 90 mmHg) and no evidence of right ventricular dysfunction.
- *Submassive PE*: Normotensive patients (SBP ≥ 90 mmHg) with evidence of right ventricular dysfunction.
- *Massive PE:* Patient is hypotensive or in cardiogenic shock (SBP < 90 mmHg) or cardiac arrest or there is fall in systolic BP by greater than 40 mm Hg; for at least 15 min.

Stable PE can be managed in hospital or on an outpatient basis with anticoagulation either with unfractionated heparin (UFH) or low molecular weight heparin (LMWH) or fondaparinux. Massive and sub-massive PE, however, carry high mortality; modalities to achieve early reperfusion of the pulmonary arteries may be life saving by reversing the right ventricular dysfunction. The various options available are thrombolysis, surgical embolectomy and percutaneous catheter embolectomy.

Anticoagulant Therapy

Anticoagulant treatment: It plays a critical role in the management of patients with PE and is required universally, regardless of whether they have undergone re-perfusion therapy for massive and sub-massive PE. Anticoagulants help in preventing formation of new thrombus, death and recurrent events with an acceptable rate of bleeding complications. The agents that are used for anticoagulation are as follows:

1. Unfractionated Heparin (UFH): UFH acts by binding to antithrombin and catalyzing the inactivation of thrombin factor Xa and other clotting factors. Besides, it also binds with other plasma proteins resulting in unpredictable pharmacokinetic and pharmacodynamic properties which can lead to non-hemorrhagic side effects, such as heparin-induced thrombocytopenia (HIT) and osteoporosis. Since the anticoagulant effect of UFH can rapidly be reversed, it is the agent of choice for patients with PE who are at high-risk of bleeding.

TABLE 126.8: Regimens of heparin therapy[70-73]

Intravenous route	*Subcutaneous route*
• 5,000 U bolus followed by 32,000 U/day infusion OR • 80 U/kg bolus followed by 18U/kg/hr infusion	• IV bolus of 5,000 U followed by 250 U/kg twice daily OR • Initial dose of 333 U/kg subcutaneously followed by 250 U/kg twice daily

Different regimens of heparin therapy[71-74] are practised by intravenous and subcutaneous routes (Table 126.8).

For the intravenous regimen, the bolus dose followed by continuous infusion is titrated to a target activated partial thromboplastin time of 1.5–2.5 times of control (approximately 60–80 seconds). The first measurement of APTT should be performed 4–6 hours after starting treatment to ensure adequate anticoagulation and repeated 3 hours after every change of dose and subsequently at least daily after target therapeutic dose is reached. Dosing based on patient's body weight is preferred to a standard regimen; it causes fewer fluctuations in APTT and achieves a therapeutic level more quickly with a shorter warfarin overlap. Subcutaneous heparin does not require frequent monitoring, unlike with IV dosing schedule, and is found to be as safe and effective as weight adjusted LMWH.[74]

The important complications associated with heparin use are bleeding, immune mediated platelet activation leading to HIT and osteoporosis. Sometimes uncommon dermatological side effects such as necrosis, alopecia and hypersensitivity are encountered. HIT is usually seen 4–14 days after heparin therapy, and can lead to major bleeding and thrombotic complications. HIT does not respond to platelet transfusion, heparin must be stopped. HIT may respond to plasmapheresis.

2. Low molecular weight heparin: Low molecular weight heparins are derived from UFH by chemical or enzymatic depolymerization. LMWH preparations have more predictable pharmacokinetic and pharmacodynamic properties have a longer half-life than heparin, and a lower risk of non-hemorrhagic side effects. Trials have confirmed the efficacy of LMWH administered subcutaneously, it has the advantages of a simple subcutaneous administration, without requiring laboratory monitoring. Low molecular weight heparins should be given with care in patients with renal failure. Intravenous unfractionated heparin may be the preferred mode

of initial anticoagulation for patients with severe renal impairment (creatinine clearance < 30 ml/min), and with severe risk of bleeding. For all other cases of acute PE, unfractionated heparin can be replaced by LMWH given subcutaneously at weight-adjusted doses without monitoring[15] (Table 126.9).

3. Fondaparinux: It is a synthetic polysaccharide with anti-Xa activity. It has been shown to be as effective as heparin and is not associated with HIT. Dosage given once daily is calculated for the body weight. It is contraindicated in severe renal failure (creatinine clearance < 30 ml/min).

Rapid anticoagulation can be achieved with parenteral anticoagulants such as intravenous UFH, fixed dose subcutaneous UFH, subcutaneous LMWH or subcutaneous fondaparinux. Anticoagulation should be initiated without delay in patients with confirmed PE and those with a high or intermediate clinical probability of PE, while awaiting definitive diagnostic confirmation (in the absence of any contraindication).[15] Treatment with parenteral anticoagulants along with (in confirmed cases of PE) or followed by (in patients with high clinical probability, after confirmation), vitamin K antagonists (VKA) (warfarin) are safe and effective therapeutic options for patients with PE. Parenteral anticoagulants should be given for oticast, 5 days and until the adequate maintenance anticoagulation with warfarin is achieved, i.e. international normalized ratio (INR) between 2 and 3 for greater than 24 hours.[75]

Long-term anticoagulation: Long-term anticoagulation to prevent clot recurrence is usually achieved by oral VKA—warfarin or acenocoumarol. Long-term treatment should be initiated once PE has been reliably confirmed. Oral anticoagulation with warfarin is instituted with dose between 5 mg and 10 mg preferably on the first treatment day, along with parenteral anticoagulants with subsequent dosing based on the INR values.

Studies performed in hospitalized patients showed that starting warfarin at a dose of 5 mg was associated with less excessive anticoagulation compared with 10 mg, although therapeutic INR (> 1.9) was achieved 1.4 days sooner with 10 mg protocol.[76,77] Clot recurrence, bleeding events and morbidity profiles did not differ in two groups. Taken together, these data suggest that warfarin can usually be started at a dose of 10 mg in younger patients (e.g. ≤ 60 years), and otherwise healthy outpatients and at a dose of 5 mg in older patients and in those who are hospitalized. Subsequent doses should be adjusted to maintain the INR at a target of 2.5 (range 2.0 to 3.0).[15] We practice a specific recommended dosage schedule to initiate warfarin with 5 mg/day[78] (Fig. 126.10). Similar dosage schedule is also available for 10 mg per day.[77]

TABLE 126.9: Dosage schedule for subcutaneous administration of low molecular weight heparins and fondaparinux

LMWH	*Dosage*
enoxaparin	1.0 mg/kg every 12 hr or 1.5 mg/kg once daily
tinzaparin	175 U/kg once daily
daltaperin	200 U/kg once daily
fondaparinux	5 mg (body weight ≤ 50 kg) once daily dosage 7.5 mg (body weight 50–100 kg) 10 mg (body weight > 100 kg)

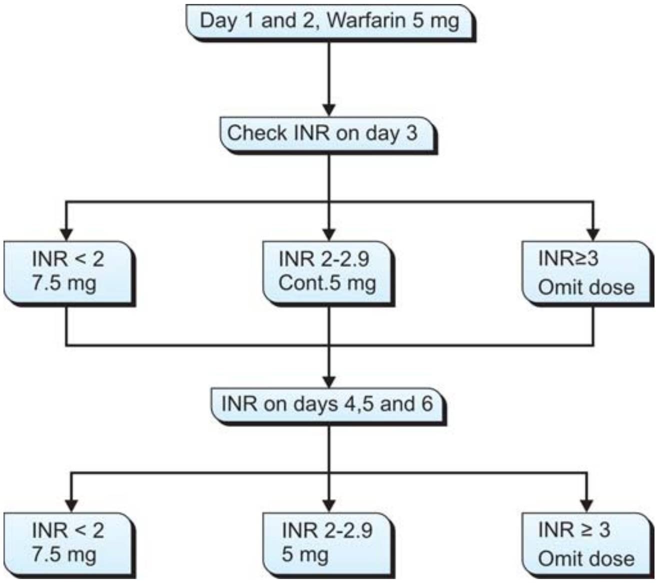

Fig. 126.10: Dosage schedule for initiation of warfarin therapy with 5 mg per day (as practiced in the department of Pulmonary Medicine, Christian Medical College Hospital, Vellore, India)

Monitoring of Oral Anticoagulants

In patients beginning VKA therapy, INR should be monitored after the initial two or three doses of oral anticoagulation therapy. For patients who are receiving a stable dose of oral anticoagulants, monitoring should be done at an interval of no longer than every four weeks.[79]

Duration of Anticoagulation Therapy

Duration of anticoagulant treatment in a particular patient should be ascertained depending on the risk benefit assessment between the estimated risk of recurrence after treatment discontinuation and the risk of bleeding complications, while on treatment. When there are transient risk factors for venous thromboembolism, such as the postoperative period, recurrence during and after treatment is unusual. Recurrent embolism in the absence of a recurrent or new risk factor should be treated with long-term anticoagulation. In patients with persisting underlying risk factors, such as deficiency of antithrombin III, protein C or protein S, the anticoagulation is usually prolonged to several years, possibly lifelong. Specific recommendations on the duration of anticoagulation are based on the onset of and conditions associated with PE (Table 126.10).[15]

Thrombolytic Therapy

Thrombolytic therapy is recommended as the first line treatment for patients with massive PE (hemodynamic compromise/imminent cardiac arrest). Thrombolytic therapy should be instituted at the earliest in such patients provided there are no contraindications,[80] pertaining to risk of bleeding (Table 126.11). The therapy not only helps in achieving rapid resolution of PE; but also rapid hemodynamic improvement. It has no role in the management of haemodynamically stable patients, except perhaps in the subgroup of patients with right ventricular dysfunction but normal systemic arterial pressure, where there is some evidence for its efficacy. Thrombolytic treatment is most effective when administered soon after PE, but benefit may extend for up to 14 days from the onset of symptoms.[17] While thrombolysis may be life saving in massive and submassive PE, the extent of long-term survival and reduction in mortality at 90 days remains unclear.[81] There are several thrombolytic agents with different dosage schedule which are commonly used (Table 126.12). Drawbacks of thrombolytic therapy are high cost, risk of severe and often fatal bleeding and allergic reactions (specifically to streptokinase).

Surgical Management

Surgical Embolectomy

Surgical embolectomy has been reserved for a selective group of patients who have massive PE with hemodynamic instability requiring cardiopulmonary resuscitation or who have failed thrombolytic therapy or have contraindications to its use. It may also be performed in patients with patent foramen ovale and intra cardiac thrombi.[82, 83] However, this procedure should be attempted only at centers with the necessary skills and experience.

Catheter Embolectomy

Catheter embolectomy or fragmentation of proximal pulmonary arterial clots may be considered as an alternative to surgical treatment in high-risk PE patients when thrombolysis is absolutely contraindicated or has failed or if patient is unwilling for surgical embolectomy.[15]

Inferior Vena Caval Filters

Inferior Vena Caval (IVC) filter devices placed in the inferior vena cava protect the pulmonary circulation from emboli. The routine use of IVC filters in patients with PE is not recommended, since they are associated with complications and late sequelae, including recurrent DVT episodes and development of the post-thrombotic syndrome. The two main indications for the use of filters are absolute contraindications to anticoagulation and high risk of VTE recurrence.

TABLE 126.10: Recommendations for long-term anticoagulation[15]

Thromboembolism	*Duration*
PE secondary to a transient (reversible) risk factor	3 months
Unprovoked PE	At least 3 months
First episode of unprovoked PE and low risk of bleeding, and in whom stable anticoagulation can be achieved	May be considered for long-term anticoagulation
Second episode of unprovoked PE	Long-term anticoagulation
PE and cancer	LMWH should be considered for the first 3 to 6 months. After this period, anticoagulant therapy with VKA or LMWH should be continued indefinitely or until the cancer is cured

TABLE 126.11: Contraindications for thrombolytic therapy[15]

Absolute	*Relative*
• Hemorrhagic stroke or stroke of unknown origin at anytime • Ischemic stroke in preceding six months • Central nervous system damage or neoplasm • Recent major trauma/surgery/ head injury (with in preceding three weeks) • Gastrointestinal bleeding within the last month • Known active bleeding	• Transient ischemic attack in preceding six months • Oral anticoagulant therapy • Pregnancy or within one week postpartum • Non-compressible punctures • Traumatic resuscitation • Refractory hypertension (systolic blood pressure > 180 mmHg) • Advanced liver disease • Infective endocarditis • Active peptic ulcer

TABLE 126.12: Thrombolytic agents and dosage schedule

Thrombolytic agent	*Dosage schedule*	*Advantages/Disadvantages*
Streptokinase	250000 IU as a loading dose over 30 min, followed by 100000 IU/h over 12–24hr *Accelerated regimen*:1.5 million IU over 2hr	• Cheap • Antigenic and hypotensive • Risk of allergic/anaphylactoid reaction on re-exposure
Urokinase	4400 IU/kg as a loading dose over 10 min, followed by 4400 IU/kg/h over 12–24hr *Accelerated regimen*:3 million IU over 2hr	• Fewer complications • Unlike streptokinase, no risk of inactivation by antibodies
Recombinant tissue plasminogen activator (rtPA)	100 mg over 2 hour or 0.6 mg/kg over 15 min (maximum dose 50 mg)	• Short infusion time • Not associated with allergic reactions or hypotension • Expensive

Pulmonary Vascular Malformations

Gautam Ahluwalia

INTRODUCTION

The diagnosis of pulmonary vascular malformations (Table 127.1) has revolutionized with the advent of multidetector computed tomography (MDCT).[1] The focus of this chapter is on pulmonary arteriovenous malformation (PAVM). Though PAVMs are not very common, they constitute an important differential diagnosis in patients presenting with hypoxemia, paradoxical embolism and nodules on chest radiographs. A high level of the index of suspicion is therefore required while evaluating patients with pulmonary symptoms.

PAVM are also known as pulmonary telangiectasias, cavernous angiomas of the lung, pulmonary arteriovenous fistulae or aneurysms.[2] Most PAVMs are congenital in nature. However, these abnormalities can also develop later in life as acquired conditions. PAVMs occur more frequently in women as compared to men (Table 127.2). The male:female ratio is 1:2. In neonates, there is male preponderance.[2,3]

Hereditary Hemorrhagic Telangiectasias or Rendu-Osler-Weber syndrome

This syndrome is named after three physicians (Rendu-Osler-Weber) who first described hereditary hemorrhagic telangiectasias (HHT) in the early 19th century. Almost every three in four cases of PAVMs have associated HHT. Conversely, approximately one in every four cases of HHT has PAVM.

HHT is a syndrome encompassing arteriovenous malformations in nose (>95%), skin (>80%), lungs (>30%), gastrointestinal tract (>30%), liver (>30%), and brain (>10%).[4,5] Diagnosis is generally established on the basis of Curacao criteria[6] (Table 127.3). HHT has an autosomal dominant inheritance with an age-related penetrance; all patients manifest the disease by the age of 40 years.[7] It is important to appreciate that arteriovenous malformation (AVM) in HHT (though present from birth) manifest clinically only in adult life after the AVM vessels have been exposed to pressure in the initial decades of life. The early clinical features include the appearance of

TABLE 127.3: Curacao Criteria for the Diagnosis of Hereditary Hemorrhagic Telangiectasia

i. History of epistaxis
ii. Superficial telangiectasias in nose, lips, oral cavity and fingers
iii. Visceral arteriovenous malformations in pulmonary, gastrointestinal, brain or spinal cord
iv. Family history of first degree relative fulfilling the diagnostic criteria for HHT#

Definite diagnosis requires 3 out of 4 criteria
Possible diagnosis requires 2 out of 4 criteria

#Hereditary hemorrhagic telangiectasia

cutaneous telangiectasia or epistaxis. Later on, the patients may present with dyspnea, pulmonary hemorrhage or obscure gastrointestinal bleeding.[2]

Genetic testing is an important adjunct in the diagnosis of HHT. Most patients show mutations in one out of three genes: ENG (endoglin) associated with HHT type 1 and ACVRL1 with HHT type 2. ENG is a transforming growth factor beta (TGF-beta) binding protein that has been identified on chromosome 9. ACVRL1 or activin receptor-like kinase 1 has been mapped to chromosome 12. Mutations in MDAH4 encoding SMAD4 resulting in overlap juvenile polyposis/HHT syndrome and an HHT locus on chromosome 5 has also been described. TGF-beta has a role in modulating vascular phenomena like angiogenesis, induction of endothelial mitogens response in cells to vascular insults. Therefore, aberrations in TGF-beta result in anatomical arteriovenous malformations.[2,4,8,9]

PATHOGENESIS

By definition, telangiectasia is a localized tortuous enlargement of the postcapillary venule with perivascular lymphocytic infiltration and smooth muscle proliferation. AVM is a direct association between the pulmonary artery and the pulmonary vein with aneurysmal enlargement of the feeding artery.[10] It has been hypothesized that in PAVM, there is incomplete resorption of vascular septae, which demarcate arterial and venous plexuses during fetal development.[11] Other investigators have postulated a defect in the terminal arterial loop, which results in dilatation of thin-walled capillary sacs.[12]

Almost two out of three PAVM occur in the lower lobes, and three out of four patients have unilateral disease. Approximately, one in three patients has multiple PAVM and half of those with multiple lesions have bilateral disease. Most PAVMs are of 1–5 cm in dimensions and involve the pleura.[2,13] They are classified as simple or complex depending on the number of feeding arteries and the draining veins.[14] Simple PAVMs have single feeding artery and a single vein, whereas complex PAVMs have multiple feeding arteries and draining veins. Almost 90% PAVM are of simple type, supplied by the pulmonary artery and PAVM drain into the left atrium. Simple PAVM predominantly occur in the lower lobe, while the complex PAVM occur in the lingula and the right middle lobe.[10]

Anatomically, PAVMs have one of the three characteristic appearances: (a) large single sac; (b) plexiform mass of dilated vascular channels; or (c) direct tortuous communication between artery and vein.[11,13] Pathologically, they consist of two elements —vascular channels lined with endothelium form the first element and the connective tissue stroma with no connection with lung parenchyma form the second element. Most PAVMs have paper thin walls, similar to the AVMs occurring in other parts of the body. Occasionally, PAVM may become calcified or contain a thrombus.[11,13,15]

CLINICAL FEATURES

In early life, patients with PAVM are asymptomatic or may present with cyanosis, cardiac failure or respiratory failure. Most patients become symptomatic in the fourth or the fifth decade. Symptoms occur more frequently in patients with PAVM and HHT than in patients with PAVM alone.[16] Moreover, symptoms correlate with the size and number of PAVM. Single and less than 2 cm PAVM are asymptomatic. Patients with multiple PAVMs have a higher probability of presence of symptoms.[16]

Epistaxis is the most common symptom in PAVM. Epistaxis may precede the development of external telangiectasia by 10 to 30 years in HHT.[17] Epistaxis may occur spontaneously or result from minor trauma to the nasal telangiectasia present. One in two patients with HHT develop epistaxis in the first two decades of life with almost all the patients developing it by the fifth decade.[16] The presence of lung nodules (PAVM) and the history of recurrent epistaxis should raise the suspicion of HHT.[4]

Dyspnea is the next common symptom after epistaxis. It is most frequently observed with large or multiple PAVM. Platypnea is another characteristic pulmonary symptom, although it is also observed in other conditions. Hemoptysis is the third most common symptom after epistaxis and dyspnea.[18,19] Gastrointestinal hemorrhage occurs in 20 to 30% patients. This symptom manifests in later life with 50% patients developing between 30 and 58 years and the remaining after the age of 58 years.[17] Infrequently, occult bleeding from extrapulmonary sources, including from superficial telangiectasias over skin and mucosa may result in iron-deficiency anemia.[20] Many nonspecific symptoms may occur from complications, such as hypoxemia, polycythemia or cerebrovascular accidents due to the presence of AVM in the brain.

On general physical examination, superficial telangiectasia present on face, oral cavity, chest and upper extremities are the sole findings in these patients. The predominant skin lesions are found on the lower lip, tongue, nose, and skin. The HHT lesions of 1 to 3 mm size are slightly rounded with dendrite-like projections, ruby-colored and sharply demarcated from adjacent skin and mucosa. Unlike the flat and readily blanchable spider nevi in chronic liver disease, the telangiectasia of HHT are papular and do not completely blanch with pressure.[21,22] PAVM patients with significant hypoxemia develop cyanosis and clubbing, almost all patients with PAVM and dyspnea manifest clubbing.[2,18,19]

On chest examination, murmurs or bruits increasing on inspiration are heard in almost one out of two patients with PAVM.[19] The murmurs also increase when the PAVM assumes a gravitationally dependent position. Though the triad of dyspnea, clubbing and cyanosis is considered specific for PAVM, it is observed in only 10% cases.[23]

INVESTIGATIONS

On arterial blood gas analysis, hypoxemia especially orthodeoxia (decrease in saturation from supine to sitting position) are observed in PAVM. Pulmonary function tests have no role in the diagnosis.

Chest radiography is the initial investigation raising the suspicion of PAVM in a patient. It may reveal a lobulated and sharply defined pulmonary nodule in the lower lobe. The size of the nodule which is usually single, varies from 1 to 5 cm. Smaller PAVM may reveal only a nonspecific increase in pulmonary vascular markings, which may wax and wane over a period of time.[24,25] On fluoroscopy, PAVM lesions in the lung reveal pulsations during Valsalva maneuver.[26] Contrast echocardiography is an excellent tool for the evaluation of intrapulmonary shunts. The contrast bubbles injected in the peripheral vein are visualized in the left atrium after a delay of three to eight cardiac cycles (2–5 seconds) as compared to an intracardiac shunt when they are visualized in the left atrium within one cardiac cycle of appearing in the right atrium.[27,28]

MDCT has become the investigation of choice. The high-resolution volumetric images can be attained with a single breath hold. Moreover, three-dimensional reconstruction of the lesion on MDCT assists in the characterization of the vascular lesions.[1] Smaller lesions missed on the chest radiograph can be diagnosed by MDCT. This modality also helps in the differentiation of PAVM from other vascular lesions of the lung (Table 127.1). The use of contrast as a timed bolus, can help to delineate the arterial and venous phases to further characterize the feeding arterial supply and venous drainage.[29]

Magnetic resonance imaging has a limited sensitivity and specificity for PAVM due to the overlap of signals with the adjacent lung parenchyma.[30] Prior to the availability of advanced MDCT, conventional pulmonary angiography was necessary to confirm the diagnosis of PAVM. Over the years, digital subtraction angiography has replaced conventional angiography.[31]

Central nervous system involvement is the most commonly reported complication in patients with PAVM (Table 127.4). Paradoxical embolism is the most plausible mechanism for noninfectious cerebrovascular accidents.[32,33]

MANAGEMENT

One in four PAVM slowly enlarge in size, whereas the remaining lesions are unchanged over years.[16,17] The

Paradoxical embolization
Symptomatic hypoxemia
Feeding vessel more than 3 mm or larger
Progressive enlargement

growth rate varies from 5 to 10 mm every 5 to 15 years. It has also been observed that enlargement is more common in patients with HHT compared to patients without HHT. The main modalities of therapy include surgery and embolotherapy[34,35] (Table 127.5).

Till the late 1970's, surgery was the mainstay of treatment of PAVM. The various procedures included local excision, segment resection, lobectomy or pneumonectomy. In patients unfit for surgery, the transaction of pulmonary artery was also used as a treatment modality.[36] Video-assisted thoracoscopic surgery is a preferred choice.[37]

Embolization of the feeding artery was first used in the year 1977. The embolic material includes vascular plugs, coils, balloons and alcohol. Currently, embolotherapy is the modality of choice.[38,39] It avoids general anesthesia and there is no loss of pulmonary parenchyma. It is also the procedure of choice in multiple and/or bilateral PAVM. As compared to surgery, periprocedural mortality and morbidity with embolization is almost negligible.[40,41] There is no role of hormonal therapy, unlike anecdotal reports in patient with AVM of other regions.[2] The role of antibiotic prophylaxis to avoid the chances of cerebral abscess needs emphasis before dental and surgical procedures in these patients.[2]

OTHER PULMONARY VASCULAR MALFORMATIONS

Many congenital and acquired abnormalities may affect the pulmonary arteries in adults.[42-51] Congenital stenosis of pulmonary arteries (proximal interruption, anomalous origin of the left pulmonary artery or pulmonary artery sling) may be discovered incidentally during chest radiography or MDCT. Acquired anomalies may generally include the diffuse or focal enlargement of pulmonary arteries. The acquired abnormalities commonly result from causes, such as pulmonary hypertension, pulmonary artery aneurysm and intravascular pulmonary metastasis.[42]

Congenital Pulmonary Artery Aneurysm and Pseudoaneurysm

Most pulmonary artery aneurysms and pseudoaneurysms are caused by trauma (including the iatrogenic causes, such as the malpositioned Swan-Ganz catheters, and chest tube insertion), infection (fungal, tuberculosis, pyogenic) and vasculitis (Behçet's syndrome). The pulmonary artery aneurysms due to tuberculosis known as Rasmussen aneurysms generally occur in the upper lobe. Pulmonary artery aneurysm and pseudoaneurysm may sometimes occur in the presence of pulmonary hypertension, congenital pulmonary stenosis, neoplasm (bronchogenic carcinoma) and connective tissue disease (Marfan syndrome). The recognition of pulmonary artery aneurysms and pseudoaneurysms is important because of the high risk of rupture related morbidity and mortality.[43]

Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) is a congenital disorder characterized by total mixing of systemic venous and pulmonary venous blood within the heart. This complete mixing of venous blood produces cyanosis. In contrast, partial anomalous pulmonary venous return (PAPVR) is usually an acyanotic condition. Anatomically, these are vascular malformations of the pulmonary circuit. However, as a matter of convention both these entities are considered as congenital heart diseases.

Bronchopulmonary Sequestration

Bronchopulmonary sequestration (BPS) is a solid or cystic mass of nonfunctioning lung tissue with an anomalous systemic blood supply. There is no tracheobronchial connection with the sequestrated lobe/segment. Both the intrapulmonary (more common) and extrapulmonary forms are commonly seen on the left side (intrapulmonary occurring more frequently in left lower lobe). In fact, a high index of suspicion is required to suspect these conditions to enable an early diagnosis on MDCT.[52,53]

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM), earlier known as congenital cystic adenomatoid malformation (CCAM), is an uncommon developmental abnormality of the lower respiratory tract. The patient may present with respiratory distress in the neonatal period or remain asymptomatic until later in life. Many cases are now detected by routine prenatal ultrasound examination, more recently by fetal magnetic resonance imaging. CPAMs result from abnormalities of branching morphogenesis of the lung. The different types of CPAMs are postulated to originate at different levels of the tracheobronchial tree and at different stages of lung development, possibly influenced by in utero airway obstruction and/or atresia. Surgical resection is the only definitive treatment.[54-57]

RESPIRATORY SLEEP DISORDERS

Ashutosh Aggarwal

128

Approach to Respiratory Sleep Disorders

Ahmad Abdelwahed, Jeremy A Weingarten

INTRODUCTION

Disorders of respiration during sleep are common in the general adult population. The clinical spectrum of respiratory sleep disorders includes obstructive sleep apnea, central sleep apnea, nocturnal hypoventilation and hypoxemia, and nocturnal manifestations of general pulmonary diseases such as asthma and chronic obstructive pulmonary disease. The evaluation of an individual suspected of a respiratory sleep disorder includes an extensive sleep history, physical examination and diagnostic testing. Controversy exists regarding the utilization of in-lab (laboratory) versus home nocturnal polysomnography; however, in-lab sleep studies remain the diagnostic "gold standard". Screening questionnaires may add information to the sleep evaluation, but findings must be confirmed with other diagnostic modalities. The clinical manifestations and issues related to obstructive airways disease and alveolar hypoventilation syndromes during sleep are discussed at the end of the chapter.

SLEEP HISTORY

Sleep complaints are varied and can often be attributed to respiratory sleep disorders. A common complaint of individuals presenting to a sleep clinic is insomnia, characterized as difficulty in initiating sleep, maintaining sleep, or a generalized nonrestorative sleep; the prevalence of comorbid insomnia in patients with obstructive sleep apnea (OSA) ranges from 39 to 55%.[1] Although insomnia is often related to comorbid psychiatric disease, medical disease or an idiopathic etiology, patients with respiratory sleep disorders often perceive their inability to sleep as insomnia and do not make the connection between their complaints and breathing abnormalities during sleep. Poor sleep quality, often described as unrefreshing and restlessness, is another common complaint of individuals with respiratory sleep disturbances; frequent nocturnal arousals due to respiratory events result in poorly consolidated sleep in these individuals. Excessive daytime sleepiness, a cardinal manifestation of OSA and other primary sleep disorders, is a major reason for seeking out a sleep specialist; frequent nocturnal arousals and poorly consolidated sleep, despite at times prolonged time in bed, can account for this common complaint. Changes in cognition associated with disrupted sleep include deficits in vigilance, executive function and coordination.[2] Finally, disruption of a bed partner's sleep due to the nocturnal activities of the patient is a common reason for individuals to undergo sleep evaluation; loud snoring, restlessness, choking sounds and limb movements/kicking are all common complaints of bed partners of individuals with respiratory sleep disorders (Table 128.1).

When directly queried, specific events reported by the patient may be clues to a diagnosis of a respiratory disorder during sleep. Snoring is a near universal complaint in people with OSA and can often be quite disruptive to individuals who sleep in close proximity to the patient. Although snoring is present primarily during sleep, patients can often perceive snoring resulting in a respiratory effort-related arousal (RERA) and also complain of loud breathing and snoring while awake. Choking and gasping during nocturnal arousal is caused by frank obstructive events; the patient

TABLE 128.1: Common complaints of patients and bed partners

Common sleep complaints	*Common bed partner complaints*
Snoring	Disruptive/crescendo snoring
Excessive daytime sleepiness	Restlessness
Poor sleep quality	Choking/gasping
Frequent nocturnal arousals	Limb movements/kicking bed partner
Insomnia	Concern of breathing cessation
Morning dry mouth	
Morning headache	
Nocturia	
Palpitations	
Cognitive deficits	

increases respiratory effort against a subtotally or totally occluded glottis, with subsequent opening of the glottis on arousal resulting in a loud snort. Morning dry mouth is attributed to increased airflow through the oropharynx. Morning headache is often a manifestation of sleep-related hypercapnia in individuals whose respiratory sleep disorder is associated with nocturnal alveolar hypoventilation. Nocturia has been associated with OSA and is felt to be due to intrathoracic pressure changes and consequent release of natriuretic hormones during obstructive events.[3] Sympathetic surges during respiratory events result in frequent heart rate accelerations on electrocardiogram and symptomatic palpitations. Finally, limb movements during sleep are common physical manifestation of the arousal response associated with respiratory events and does not necessarily represent an alternate primary sleep disorder such as periodic limb movement disorder.

It is crucial during the sleep history to ascertain sleep positioning of the patient and its relationship to respiratory complaints during sleep. In imaging studies of individuals with OSA, the retropalatal and retroglossal space has been shown to be the major site of obstruction;[4] gravitational effect on the tongue base and palate while the patient is in the supine position functionally reduces the cross-sectional area of the upper airway and often exacerbates symptoms of OSA, particularly snoring and obstructive events. Although patients often do not realize the reasons, they prefer to sleep in the nonsupine position. It is likely that in individuals with OSA, sleep in the nonsupine position is a protective mechanism to reduce the likelihood of obstruction.

As patients present with varied and sometimes bizarre sleep complaints, it is important to have a working knowledge of the manifestations of other sleep disorders in order to differentiate these problems from more typical respiratory sleep disorders. While limb movements during sleep may be a part of the arousal response to obstructive respiratory events, they may also represent a primary sleep disorder, such as periodic limb movement disorder or a seizure disorder. The differential diagnosis of hypersomnia, one of the primary complaints seen in sleep clinic, is varied and includes any disorder that increases the frequency of nocturnal arousal (respiratory sleep disorders, limb movement disorders), narcolepsy, idiopathic hypersomnia and insufficient sleep syndromes (behaviorally-induced, related to psychiatric or medical disease, circadian rhythm disorders). Complaints associated with some of these alternative diagnoses elicited during the sleep history include sleep paralysis, dream enactment, somnambulism, hypnagogic and hypnopompic hallucinations, and restless legs during wakefulness/periodic limb movements during sleep.

A complete medication history is essential in evaluating the patient with sleep complaints. Respiratory suppressants, such as narcotics and benzodiazepines, may increase the risk of OSA in individuals who are at risk for this disorder. Narcotic medication is additionally associated with opioid-induced central sleep apnea syndrome.[5] The use of REM-suppressant medication may decrease the severity of an individual's sleep-disordered breathing. Individuals with OSA are especially vulnerable to obstructive events during REM sleep; therefore, the use of REM-suppressant medication decreases an individual's opportunity to have obstructive events. The most common REM-suppressants are antidepressant medications. Selective serotonin reuptake inhibitors (SSRIs), in addition to being potent REM-suppressants, are known to increase the frequency of limb movements during sleep, further complicating the individual's diagnostic evaluation.

PHYSICAL EXAMINATION FOR RESPIRATORY SLEEP DISORDERS

Examination of the upper airway is an essential component of the evaluation for respiratory sleep disorders. Although complete evaluation of the upper airway requires endoscopic visualization of structures and radiologic imaging (X-ray cephalometry, computed tomography, and magnetic resonance imaging), a general physical examination in the pulmonologist or sleep specialist's office often provides important clues to the diagnosis of respiratory sleep disorders and will guide future diagnostic modalities. The Mallampati classification system was initially developed in the anesthesia literature to predict the difficulty of direct laryngoscopy; this scoring system has been shown to be an independent predictor of the presence and severity of OSA in patients with suspected respiratory sleep disorders.[6]

The Mallampati grade (I–IV) is determined by asking the patient to open the mouth and protrude the tongue without emitting sound. The grading is as follows:

I. Soft palate and entire uvula visualized.
II. Soft palate and portion of the uvula visualized.
III. Soft palate visible only (base of the uvula may be seen).
IV. Soft palate not visualized (hard palate only visible structure).

While visualizing the posterior pharynx, assessment of the size of the tonsils and presence of macroglossia may be made. Examination of the nose to determine the presence of septal deviation, external nasal deviation, inflamed mucosa and patency of nares should be performed to determine the contribution of decreased nasopharyngeal airflow to respiratory symptoms. Craniofacial features should be evaluated such as the presence of retrognathia or micrognathia. Finally, evaluation of the neck should be performed to determine the presence of thyroid disease and measure neck circumference; increasing neck circumference has been associated with greater risk of OSA.[7]

While the upper airway examination is an essential component in the evaluation of the potential risk of OSA, other clues to the diagnosis of a respiratory sleep disorder and the clinical sequelae of such disorders can be discerned by a more general physical examination. Cardiac evaluation is essential to determine the presence of signs of right heart failure (right ventricular heave, loud P2) and left heart failure (S3, S4, displaced PMI, murmur due to valvular disease). Respiratory examination may demonstrate coexistent obstructive airways disease or neurologic disease (diaphragmatic paralysis) that may contribute to nocturnal hypoventilation and subsequent gas exchange abnormalities during sleep. Abdominal examination may suggest congestive hepatopathy due to cor pulmonale. Extremity examination may demonstrate peripheral edema, clubbing and/or cyanosis, which may lead to further cardiopulmonary evaluation. Finally, neurologic evaluation is important to determine the risk of nocturnal hypoventilation from neuromuscular disease and central sleep apnea from cerebrovascular disease (as manifested by focal neurologic deficits). Although the findings on physical examination are nonspecific, they are essential for complete evaluation of the patient presenting to sleep clinic.

NOCTURNAL POLYSOMNOGRAPHY

Although clinical prediction models used to estimate the presence of OSA in various populations have been evaluated, in-laboratory nocturnal polysomnography (PSG) remains the “gold standard” diagnostic method in determining the presence of a sleep-related breathing disorder. In its most recent practice parameters,[8] the American Academy of Sleep Medicine (AASM) stated that PSG is routinely indicated for the diagnosis of sleep-related breathing disorders (Table 128.2). Multiple sleep latency testing (MSLT), an adjunct in-laboratory test during which an individual takes several naps throughout the day to objectively measure daytime sleepiness, is not indicated in the evaluation of sleep-related breathing disorders.

In-laboratory polysomnography is a complex medical procedure that enables recording and analysis of a wide spectrum of physiologic processes during sleep; the complexity of this test provides important cardiopulmonary and electromyographic information in the context of electroencephalographically derived sleep stages and body position. For a type 1 study (in-laboratory, technician supervised study), several physiologic components are monitored and recorded (Table 128.3). In addition, audiovisual recording is usually performed.

Although PSG is considered the “gold standard” for diagnosing sleep-related breathing disorders, it is not infallible. Data loss, artifacts and measurement errors may affect the analysis of the raw data. Scoring of sleep studies is performed by sleep technicians; intra- and inter-rater event recognition errors and differences in

TABLE 128.2: Indications for Polysomnography

- Obstructive sleep apnea syndrome (OSA)
- Central sleep apnea syndrome (CSA)
- Cheyne-Stokes respiratory pattern (CSR)
- Alveolar hypoventilation syndromes

Additional high level indications (2005 Statement and supported by strong evidence-based medicine)

- Positive airway pressure titration in patients with sleep-related breathing disorders
- Preoperative evaluation to determine the presence of OSA in patients before they undergo upper airway surgery for OSA
- Follow-up evaluation after upper airway surgery or utilization of an oral appliance
- Follow-up after significant weight gain or loss (10% of body weight) or when clinical response is sub-optimal
- Individuals with systolic or diastolic heart failure with nocturnal symptoms
- Those who remain symptomatic despite optimal medical therapy.

TABLE 128.3: Components of Type 1 (In-lab, technician supervised) polysomnography study

- Electroencephalography
- Electrooculography
- Electromyography (chin, anterior tibialis)
- Electrocardiography

- Pulse oximetry
- Rib cage and abdominal wall movements (inductance plethysmography)
- Snoring

respiratory event definitions among different sleep laboratories (discussed below) can result in over- or underestimation of respiratory events. Night to night variability and the "first night effect," a well described phenomenon in which individuals evaluated in the sleep lab will have poorer sleep quality on the first night when compared with successive study nights, likely affects the accuracy of PSG.[9] Regardless of potential pitfalls of in-lab PSG, it remains the most comprehensive and accurate analysis of sleep currently utilized.

Based on objective findings, we are able to classify respiratory events into apnea (obstructive, central or mixed), hypopnea, respiratory effort-related arousal (RERA), hypoventilation, and Cheyne-Stokes breathing.[10] An apnea is defined as a reduction in the amplitude of the nasal thermistor by ≥ 90% for 10 seconds; if the event is associated with respiratory effort, it is classified as obstructive; if no respiratory effort is present, it is a central event; and if it starts out without respiratory effort but which resumes in the latter portion of the event, a mixed apnea. A hypopnea, which should not be classified as obstructive, central or mixed unless quantitative measures are utilized (calibrated respiratory inductance plethysmography, esophageal manometry, or diaphragmatic/intercostal EMG), is defined as a reduction in the nasal pressure transducer amplitude by ≥ 30% for 10 seconds with a concomitant oxygen desaturation of ≥ 4%.

The alternative definition of a hypopnea, which is utilized in some sleep centers, consists of a decrease in the nasal pressure transducer amplitude by ≥ 50% lasting for 10 seconds and with either concomitant ≥ 3% drop in oxygen saturation or an EEG arousal. The number of apneas and hypopneas that occur per hour of sleep are combined to provide an apnea-hypopnea index (AHI), which is utilized as a measure of severity of disease. A RERA is defined as a period of 10 seconds of increasing respiratory effort or flattening of the nasal pressure amplitude leading to an arousal from sleep that does not meet criteria for an apnea or hypopnea; diagnosis of a RERA should be made utilizing esophageal manometry or calibrated respiratory inductance plethysmography along with the flattening of nasal pressure waveform. Conceptually, a RERA is an obstructive event in which the individual is able to maintain airflow against increasing airflow resistance by concomitantly increasing respiratory effort. The respiratory disturbance index (RDI) is the total number of apneas, hypopneas and RERAs per hour of sleep, and an alternate index of disease severity.

In clinical practice in the United States, the AHI, not the RDI, is used by insurers to determine eligibility for treatment of sleep-related breathing disorders. Hypoventilation is scored if there is an increase of ≥ 10 mm of Hg in partial pressure of arterial carbon dioxide (P_aCO_2) when compared with wake state; end-tidal CO_2 and transcutaneous CO_2 are often used as surrogates for the P_aCO_2. Cheyne-Stokes respiratory pattern is present if there are at least three consecutive cycles of crescendo-decrescendo respiratory amplitude change (flow and effort) lasting at least 10 minutes or with an AHI ≥ 5 (central apnea and hypopnea).

PORTABLE MONITORING

In-laboratory nocturnal polysomnography is the "gold standard" for diagnosing and treating sleep-disordered breathing; however, it is also a resource-intense procedure with limited capacity and thus prolonged wait-times until individuals are successfully evaluated and treated. A recent analysis evaluated the time from referral until CPAP initiation in five regions throughout the world: the United States, England, Belgium, Australia and Canada.[11] The average wait time was 2 to 60 months, with wide variability among these regions; England had the longest (range 7–60 months) and Belgium the shortest wait time (2 months). Although these data do not evaluate average wait times in other regions of the world, which may in fact have longer wait times with limited availability, it is clear that the need for decreased time to treatment for respiratory sleep disorders is a major challenge in sleep medicine.

Portable monitoring encompasses a wide spectrum of diagnostic technology utilized to determine the presence or absence of sleep-disordered breathing outside of a formal in-laboratory study. Four types of sleep monitoring devices have been defined;[12] these designations are currently used for research as well as clinical purposes. Type 1 studies are standard, attended in-laboratory polysomnography measuring all physiologic parameters described previously. Type 2 studies record the same variables as Type 1 studies (EEG, EOG, chin EMG, EKG, airflow, respiratory effort and oxygen saturation) but do not require the presence of sleep technician, nor do they require that the patient spend the night in a sleep laboratory. Type 3 studies are required to measure at least four physiologic parameters, including ventilation (respiratory effort/airflow), heart rate or EKG and oxygen saturation. Type 4 studies previously were defined as requiring 1 channel measurement (pulse oximetry, most commonly); however, the definition of a type 4 study has been changed from its original description and now requires at least three physiologic parameters, although these parameters are not fully defined.[13]

Advantages of using portable monitoring include decreased time to diagnosis of sleep-disordered breathing, improved comfort due to the patient being able to be studied in a comfortable and familiar environment, and decreased costs associated with diagnostic testing. Using a mathematical model to simulate head to head comparison of multiple diagnostic and therapeutic strategies to determine the presence of and treat OSA under various assumptions, Trikalinos and colleagues found that using a strategy of in-laboratory PSG followed by in-laboratory full night CPAP titration versus a strategy of portable monitoring followed by a full night in-home CPAP auto titration resulted in a decrease in time to diagnosis of 11.5 weeks using portable monitoring (13.6 weeks versus 2.1 weeks) and a decrease in time to CPAP titration of 22.5 weeks (27.3 versus 4.8 weeks).[14] Although the portable monitoring group had a markedly decreased total time until diagnosis and treatment, the simulation found that the false-negative rate in this group was 9% while the false-positive rate (individuals in whom CPAP titration was offered despite the absence of clinically diagnosed OSAHS) was 15% among middle aged individuals and 30% among older adults (70 years old). In the standard group (in-lablaboratory PSG and titration), the false-positive rate and false-negative rates were zero; this is an expected finding, as this modality is the "gold standard" method.

The false-positive and false-negative rates cited in the above study demonstrate a major limitation of portable monitoring. As type 3 and type 4 studies are the most common portable monitoring techniques, fewer physiologic parameters are measured and the data may underestimate or overestimate the presence and/or severity of disease. Type 3 and 4 studies do not measure electroencephalographic data, thereby preventing sleep staging; thus, total time in which the apnea-hypopnea index is determined is the total recording time instead of total sleep time. For example, if an individual has 100 respiratory events during the night, is studied by a portable device and the total recording time is 8 hours, the calculated AHI is 12.5 events per hour (mild sleep-disordered breathing); however, if the same individual has 100 respiratory events but has a complete in-laboratory study demonstrating 5 hours of total sleep time by EEG criteria despite a total recording time of 8 hours, then he/she would have a calculated AHI of 20 events per hour (moderate sleep-disordered breathing).

Another limitation of portable monitoring is the fact that data loss is likely to occur as the leads frequently fall off a patient during the course of a study; without the availability of the technical staff in the home to monitor this problem, a variable amount of data will not be captured. Although a presumptive diagnosis of a respiratory sleep disorder may be made, treatment cannot be carried out with portable monitoring, thereby limiting its clinical utility. Finally, portable monitoring has not been thoroughly studied in disorders other than obstructive sleep apnea, again limiting its utility.

The Portable Monitoring Task Force of the American Academy of Sleep Medicine has recently published clinical guidelines for the use of unattended portable monitoring for the diagnosis of obstructive sleep apnea.[15] Based on a review of the literature evaluating type 3 devices (stated as the most commonly used device in the outpatient setting), the Task Force reported that portable monitoring is indicated for the diagnosis of OSA in individuals with a high pretest probability of moderate to severe OSA in conjunction with a comprehensive sleep evaluation. Populations that should not be evaluated with portable monitoring include those with significant comorbid medical disease (including pulmonary disease, neuromuscular disease and congestive heart failure) and those suspected of having other sleep disorders (central sleep apnea, a limb movement disorder, etc.). The guidelines also made exceptions for individuals who do not meet the above criteria but cannot undergo in-laboratory polysomnography due to problems of safety, immobility, or critical illness. While there may be a role for portable monitoring in the diagnosis of OSA in high risk populations without comorbid disease, its limitations in the diagnosis and management of respiratory sleep disorders lead many to believe that it remains a suboptimal testing modality.

SLEEP QUESTIONNAIRES

Sleep questionnaires, which quantify the severity of symptomatic daytime somnolence and/or screen for the presence of OSA, assist the sleep physician in determining an individual's risk for primary sleep disorders. The Epworth Sleepiness Scale (ESS), a self-administered tool to measure subjective daytime sleepiness, is one of the most commonly utilized questionnaires in sleep medicine due to its simplicity and brevity. The original research article describing the ESS demonstrated that the severity of OSA was significantly correlated with the ESS score.[16] The ESS evaluates an individual's sleep propensity by assigning the likelihood of falling asleep on a 4-point scale (0–3) in each of eight situations, which include the following as examples: sitting and reading, watching television, sitting and talking to someone, etc. Although the ESS is a widely used measure of subjective sleepiness and an integral component of an initial sleep evaluation, it has been shown to not correlate with objective measures of sleepiness (MSLT)[17] and not be able to differentiate between primary snoring and OSA,[18] thereby limiting its usefulness in screening individuals for respiratory sleep disturbances.

A recent systematic review analyzed the accuracy of screening questionnaires in determining the presence or absence of obstructive sleep apnea diagnosed by nocturnal polysomnography (Table 128.4).[19] Potential studies were screened and determined to be eligible for the study if they utilized patient-based questionnaires as screening tools for OSA in individuals of over 18 years of age, the questionnaire's accuracy was compared with PSG results as the "gold standard" for diagnosing OSA, the definition of OSA was clearly defined as an AHI, apnea index, or RDI ≥ 5. Ten studies met inclusion in this systematic review, evaluating 1,484 subjects. The Berlin Questionnaire, Wisconsin Questionnaire and STOP and STOP-Bang questionnaires were the most frequently studied; in individuals without a history of sleep disorders, the Wisconsin Questionnaire had the highest sensitivity in determining the presence of mild OSA (95%, AHI ≥ 5) while the STOP-Bang Questionnaire, which was used in a surgical population only, had the highest sensitivity (93%) in those with moderate OSA (AHI ≥ 15). Although screening tests in general are most useful when they demonstrate high sensitivity, the tests described above are not perfect discriminating tools; the specificities of the above questionnaires are 64 and 43%, respectively. Caution, when interpreting the results of screening questionnaires for OSA, should be employed.

RESPIRATORY DISORDERS DURING SLEEP

Although sleep apnea syndromes are the most commonly diagnosed and treated disorders in a sleep medicine practice, many disease entities seen in a general pulmonary practice manifest with significant nocturnal symptoms.

Asthma

Nocturnal asthma, which is defined by a drop in forced expiratory volume in 1 second (FEV_1) of at least 15% between sleep and awake states associated with increased airway hyperresponsiveness and inflammation,[20] has gained increased awareness and is likely under-reported. In a large cross-sectional survery of nocturnal asthma symptoms in France, 81% of 13,493 patients had nocturnal symptoms;[21] although this study did not measure pulmonary function parameters, the high prevalence of subjective symptoms of individuals diagnosed with asthma remains a significant finding. Several pathophysiologic mechanisms are proposed as contributing to the etiology of nocturnal asthma symptoms, including circadian increases in inflammatory mediators (eosinophils, macrophages, $CD4^+$ lymphoctyes and leukotrienes), positional changes in lung volume and airways resistance with supine positioning for sleep, changes in the β-adrenergic receptors controlling airway tone, alterations in glucocorticoid receptor binding affinity and the association of OSA with nocturnal asthma symptoms.[20]

Genetic polymorphisms in the β-adrenergic receptor are of recent interest; it is postulated that genetic substitution of glycine for arginine at locus 16 may result in increased presence of nocturnal asthma. In a study of 47 Chinese asthmatics (25 nocturnal asthma, 22 non-

nocturnal asthma), the presence of gly/gly genotype at locus 16 was 72% in the nocturnal group and 32% in the non-nocturnal group (p=0.022).[22] In a meta-analysis that included five studies of nocturnal asthma, the presence of the glycine allele at locus 16 more than doubled the risk (OR 2.2, p<0.001) of nocturnal asthma,[23] although this polymorphism was not found to increase the overall risk of asthma in both this study and other meta analyses.[24]

Prior to focusing on the specific treatment of nocturnal symptoms of asthma, it is imperative that the patient has adhered to standard asthma therapy which ideally manages asthma symptoms throughout the course of a 24-hour period. Thus the first step in controlling nocturnal asthma symptoms includes avoidance of allergens, adequate evaluation and treatment of comorbid conditions that may potentiate asthma severity and the use of appropriate pharmacologic therapy.[25] Altering the timing of medication administration may be helpful in individuals with significant nocturnal asthma symptoms. Administration of oral prednisone at 3 PM improved morning FEV_1 and decreased blood eosinophil counts and bronchoalveolar lavage cell line counts when compared with alternately timed dosing.[26] Long-acting β-agonist therapy likely improves nocturnal symptoms and has been shown to improve quality of life measures in individuals with nocturnal asthma in a randomized controlled trial.[27] Other timed therapies may be useful in nocturnal asthma; further studies are needed.

COPD

Chronic obstructive pulmonary disease (COPD) and sleep apnea syndromes are both common disease entities in the general adult population. The presence of both COPD and OSA has been termed the "overlap syndrome" and denotes worsened nocturnal gas exchange parameters compared with either disease entity alone. Although early studies suggested that individuals with COPD had higher prevalence of OSA and vice versa, subsequent studies with improved methodologic quality proved this supposition false. The Sleep Heart Health Study (SHHS), which evaluated a large cohort of individuals sampled from several ongoing cohort studies of cardiovascular health, enrolled 5,954 subjects who underwent ambulatory PSG and spirometry.[28] After adjusting for body mass index, there was no significant difference in the presence of sleep apnea among those with and without obstructive airways disease; therefore, the presence of OSA or COPD did not increase the risk of the other disease entity to be present. Further findings from the study included:

1. In those without OSA, there was no difference in ESS, sleep latency, sleep efficiency, and sleep architecture among those with and without airways obstruction, although there was a small difference in total sleep time.
2. Individuals with the "overlap syndrome" had lower sleep efficiency than those with OSA or airways obstruction alone.

Oxygen saturation of hemoglobin is significantly affected by the presence of OSA, airways obstruction, and the "overlap syndrome". In individuals without OSA in the SHHS[28], an FEV_1/FVC ratio of 60 to 65% had a 2-fold increased risk of oxygen saturation of <90% for greater than 5% of total sleep time (OR 1.92; CI 1.1–3.34) after adjusting for potential confounders. In those with the "overlap syndrome", the odds ratio of spending >5% total sleep time below 85% oxygen saturation as compared with subjects without OSA and airways obstruction was 30, while the odds of OSA alone (without airways obstruction) was 15; thus, the "overlap syndrome" connotes a much greater degree of gas exchange abnormality when compared with OSA or airways obstruction alone. Potential pathophysiologic mechanisms for the degree of oxyhemoglobin desaturation in the overlap syndrome include altered respiratory mechanics due to lung disease, ventilation/perfusion abnormality and pulmonary parenchymal abnormalities due to underlying lung disease. Management of the overlap syndrome includes positive airway pressure (continuous or bilevel mode), pharmacologic management of airways obstruction and oxygen supplementation when indicated.

Hypoventilation/Hypoxemia Syndromes

The International Classification of Sleep Disorders

Diagnostic and Coding Manual defines sleep related hypoventilation/hypoxemia as P_aCO_2 >45 mm Hg, an oxyhemoglobin saturation of <90% for more than five minutes with a nadir of ≤85% or >30% of total sleep time with an oxygen saturation of <90%.[29] While gas exchange parameters are important for the diagnosis of hypoventilation/hypoxemia syndromes, the causes of these gas exchange abnormalities is comprised of a heterogenous group of disorders that affect the ability of the respiratory system to compensate for sleep-related changes in ventilatory control mechanisms and respiratory mechanics. This group includes neuromuscular, pulmonary and chest wall disorders and various idiopathic disorders (congenital central alveolar hypoventilation). The primary pathophysiology of nocturnal hypoxemia relates to the inability of the respiratory system to maintain adequate ventilation, resulting in an elevation of alveolar partial pressure of carbon dioxide and a subsequent reduction of alveolar oxygen, consistent with the alveolar gas equation; an alternate cause of hypoxemia likely relates to increasing ventilation and perfusion mismatch in poorly ventilated lung regions.

Clinical features of alveolar hypoventilation include poor sleep quality, nocturnal and/or morning headache, daytime sleepiness and loss of energy, decreased intellectual performance, loss of appetite and weight loss, and features of progressive right heart failure/cor pulmonale.[30] Treatment for sleep-related hypoventilation/hypoxemia syndromes is disorder specific, although noninvasive ventilation in the bilevel mode is often a necessary adjunctive measure utilized in all of these disorders; short-term improvement in clinical symptoms and the suggestion of a mortality benefit, particularly in individuals with neuromuscular disease, is present when noninvasive ventilatory support is utilized.[31]

Neuromuscular disorders that may result in nocturnal hypoventilation/hypoxemia include amyotrophic lateral sclerosis (ALS), spinal cord injury, diaphragmatic paralysis, myasthenia gravis, Eaton-Lambert syndrome, post-polio syndrome, myopathic disorders and Charcot-Marie-Tooth syndrome.[32] Individuals with ALS, a neurodegenerative disorder characterized by loss of motor neurons with resultant progressive weakness and atrophy of skeletal muscles including accessory muscles of respiration, are at risk for both diurnal and nocturnal hypoventilation/hypoxemia. In a prospective observational study of 38 patients with ALS, the forced vital capacity (FVC) decreased by a mean of 10% after six months and 71% of patients developed chronic hypoventilation by 26 months;[33] the criteria to define chronic hypoventilation included nocturnal desaturation of oxyhemoglobin saturation <88% for five consecutive minutes. Although this study did not specifically evaluate hypoventilation during sleep, it can be assumed that all patients who developed chronic hypoventilation were affected during sleep since the normal physiologic response to sleep is a mild elevation of P_aCO_2 even in the absence of disease,[34] compounding the disease related hypoventilation.

Although the diminished function of respiratory muscles is the primary defect in neuromuscular disorders during sleep, individuals with chest wall disorders (kyphoscoliosis, ankylosing spondylitis, trauma, pleural disease, history of thoracoplasty and obesity) and pulmonary disease (COPD, asthma, IPF, CF) are at risk for nocturnal hypoventilation/hypoxemia due to several additional mechanisms. During REM sleep, bursts of rapid eye movements are associated with inhibition of accessory muscles of respiration;[35] ventilation and gas exchange thus depend solely on the diaphragm. Individuals with chest wall and/or pulmonary disease may already have gas exchange abnormalities due to their underlying disease when awake; normal increases in P_aCO_2 associated with sleep onset compounds the underlying gas exchange problems, resulting in worsening hypoxemia. Obesity results in reduced chest wall compliance due to the mass load placed on the thoracic cage; the reduction in compliance is further exacerbated in the supine position, worsening ventilatory function during sleep by increasing the work of breathing.[36]

Obstructive Sleep Apnea-Hypopnea Syndrome—A Developing Countries' Perspective

Harmanjit Singh Hira

A syndromic presentation mimicking first recognized in the 19th century when Charles Dickens (1837) gave literacy description of a sleepy red-faced fat boy "Joe".[1] Burwell et al.[2] described a medical description of a Pickwickian syndrome as "obesity, somnolence, cyanosis, polycythemia, right heart failure" in 1956. It was 1964 that Gastaut et al.[3] provided the polygraphic recording of pickwickian patients' "presence of apneas during sleep". Introduction of the term "Sleep Apnea Syndrome" (SAS) in patients presenting with clinical picture as different from the pickwickian syndrome was coined by Guilleminault in 1976.[4]

An apnea is a period of time during which the breathing stops or slows to <25% of a normal breath for a period that lasts for 10 seconds or more. Hypopnea is a decrease in breathing from 69% to 26% of normal and is associated with a 4% or greater drop in the saturation of oxygen in the blood. Sleep apnea syndrome (SAS) is diagnosed when these frequent interruptions occur up to 30 times or more in an hour. Natural history of sleep apnea syndrome may be listed as: Pure snoring → snoring with occasional apneas → overt SAS → sleep apnea with daytime hypoventilation → Pickwickian syndrome.

Obstructive sleep apnea-hypopnea (OSAH) is characterized by recurrent episodes of upper airway collapse and obstruction during sleep. These episodes of obstruction are associated with recurrent oxyhemoglobin desaturations and arousals from sleep. OSAH associated with excessive daytime sleepiness (EDS) is commonly called Obstructive Sleep Apnea-Hypopnea Syndrome (OSAHS). Despite being a common disease, OSAHS is under recognized by most primary care physicians in India. Also, an estimated 80% of Americans with OSAHS are not diagnosed.[5] Central apnea syndrome occurs when the brain fails to signal the diaphragm and chest muscles to breathe. It is more common in the elderly persons.

Pathophysiology

Conceptually, the upper airway is a compliant tube, therefore, subject to collapse.[6] Most patients with OSAHS demonstrate upper airway obstruction at either the level of the soft palate (nasopharynx) or of the tongue (oropharynx) which are normally dilated as open airways (Fig. 129A.1A). Both anatomic and neuromuscular factors are important in causing obstruction. Anatomic factors (enlarged tonsils; larger volume of the tongue, soft tissue or lateral pharyngeal walls); length of the soft palate; abnormal positioning of the maxilla and mandible) decrease the cross-sectional area of the upper airway (Fig. 129A.1B) and/or increase the pressure surrounding the airway, both of which predispose the airway to collapse.[7,8]

Upper airway neuromuscular activity, including reflex activity, decreases with sleep, this decrease may be more pronounced in patients with OSAHS. Reduced ventilatory motor output to upper airway muscles is believed to be the critical initiating event leading to upper airway obstruction; this effect is most pronounced in patients with an upper airway predisposed to collapse for anatomical reasons.

Central breathing instability is a well-established factor contributing to the development of central sleep apnea, particularly in patients with severe congestive heart failure. Evidence also indicates that central breathing instability contributes to the development of OSAHS:

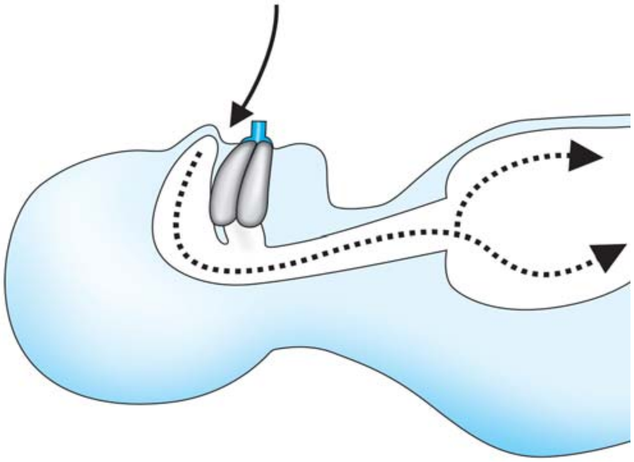

Fig. 129A.1A: Normal open upper airway (arrows). Obstruction occurs at either the level of the soft palate (nasopharynx) or at the level of the tongue (oropharynx)

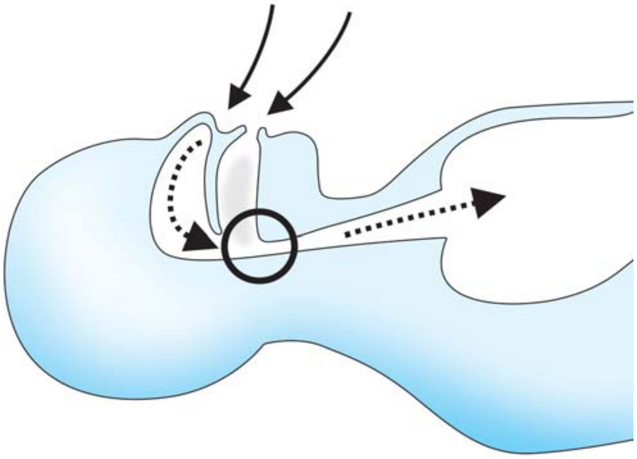

Fig. 129A.1B: Cross-sectional area of the upper airway and/or increase the pressure surrounding the airway, both of which predispose the airway to collapse to lead to closed airway marked as a black circle.

i. Upper airway obstruction in the absence of ventilatory motor output (central sleep apnea) has been observed.[9-11]

ii. Reduction in pharyngeal dilator activity has been associated with periodic breathing and hypocapnia in subjects with evidence of inspiratory flow limitation.

iii. Men have been shown to be more susceptible to the development of central sleep apnea and have a decreased responsiveness to carbon dioxide compared with women, a result consistent with the increased prevalence of OSAHS in men compared with women.

Systemic hypertension is observed in 50 to 70% of patients with OSAHS. It has been shown that patients with OSAHS had increased glucose levels and increased insulin resistance.[12] We have also observed that OSAHS is associated with increased production of reactive oxygen species and other oxidative stress biomarkers like uric acid and lactate.

Clinical Features

OSAHS is a common disease, globally and in India,[6] the estimated prevalence is 2% for women and 4% for men. The male-to-female ratio in community-based studies is 2–3:1. Three large epidemiologic studies have demonstrated that the prevalence of OSAHS in women appears to increase after menopause. The prevalence increases with age,[13] with an estimated rate as high as 65% in a community sample of people older than 65 years.[14]

Symptomatology

Symptoms of OSAHS generally begin insidiously and are often present for years before the patient is referred for evaluation. The common symptoms can be grouped as follows:

Nocturnal Symptoms

- Snoring, usually loud, habitual and bothersome to others
- Witnessed apneas, which often interrupt the snoring and end with a snort
- Gasping and choking sensations that arouse the patient from sleep
- Restless sleep, with patients often experiencing frequent arousals and tossing or turning during the night
- Increased frequency of mictuirition

Daytime Symptoms

- Not feeling refreshed upon awakening
- Morning headache, dry or sore throat
- Excessive daytime sleepiness that usually begins during quiet activities (reading, watching television). As the severity worsens, patients begin to feel sleepy during activities that generally require alertness (school, work, driving). It is the experience of the author that these patients generally sleep while waiting for their turn for examination in outpatient department.

  - EDS is most frequently assessed by a sleep physician using the Epworth Sleepiness Scale (ESS). This questionnaire is used to help determine how frequently the patient is likely to doze off in 8 frequently encountered situations.
  - An ESS score greater than 10 is generally considered sleepy. However, a 2003 study showed that an ESS score of 12 is associated with a greater propensity to fall asleep on the Multiple Sleep Latency Test (MSLT) suggesting that 12 would be a better cutoff.[15] The ESS is useful for evaluating responses to treatment; the ESS score should decrease with effective treatment.
- Daytime fatigue/tiredness: Most of the patients who do not report EDS, do complain of fatigue, having a lack of energy, or getting tired during the day. In one study of 190 patients with OSAHS, patients were more likely to report lack of energy (62%), fatigue (57%) and tiredness (61%) than sleepiness (47%).[16] When asked to choose their most significant symptom, 40% of patients chose lack of energy, compared with 22% for sleepiness.[16]
- Problems with memory, concentration and cognitive function, particularly executive functioning
- Impotence
- History of motor vehicle accident(s).

Physical Examination

The general physical examination is frequently normal, other than the presence of obesity (defined as a BMI >30 kg/m^2), an enlarged neck circumference and hypertension. Evaluation of the upper airway is required in all patients, particularly in nonobese adults with symptoms consistent with OSAHS. The following features have been associated with the presence of OSAHS:

- *Neck circumference:* A neck circumference greater than 43 cm (17 inches) in men and 37 cm (15 inches) in women has been associated with an increased risk of OSAHS.
- *Mallampati score:* This score has been used for many years to identify patients at risk for difficult tracheal intubation. Scoring is classified (Fig. 129A.2) as Class 1: Full visibility of tonsils, uvula and soft palate; Class 2: Visibility of hard and soft palate, upper portion of tonsils and uvula; Class 3: Soft and hard palate and base of the uvula are visible; and Class 4: Only hard palate visible.

The classification provides a score of 1 to 4 based on the anatomic features of the airway seen when the patient opens his or her mouth and protrudes the tongue. A 2006 study showed that for each 1 unit increase in the Mallampati score, the odds ratio of having OSAHS (defined by an AHI > 5) increased by 2.5, and the AHI increased by five events per hour.[17]

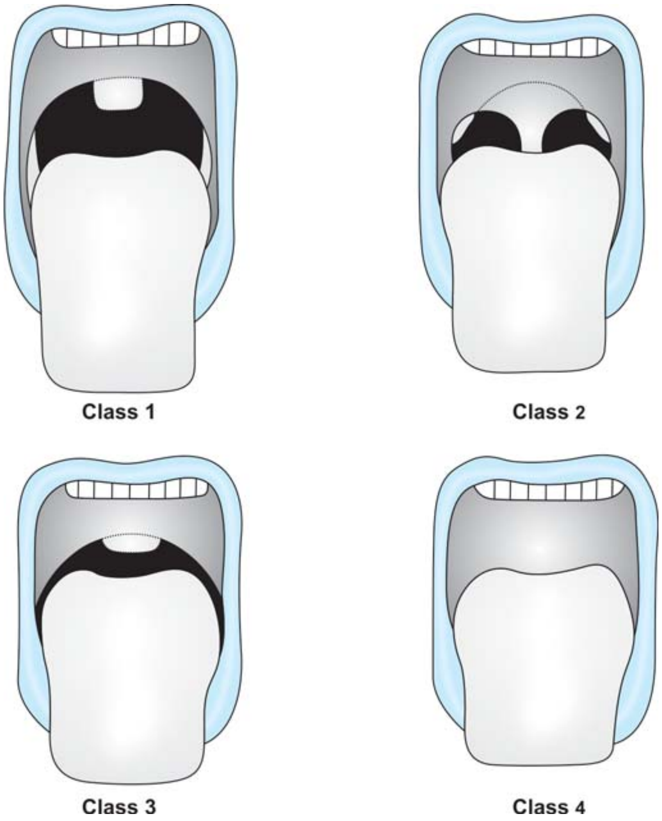

Fig. 129A.2: Shows the pictures of all four classes based on Mallampati score.

- Narrowing of the lateral airway walls, which is an independent predictor of the presence of OSAHS in men, but not women
- Enlarged ("kissing") tonsils (3^+ to 4^+) (Fig. 129A.3)
- Retrognathia or micrognathia
- Large degree of overjet
- High-arched hard palate

Causes

Obstructive sleep apnea syndrome is common in the presence of several known risk factors (Table 129A.1).

Other diseases associated with the development of OSAHS are as follows:

- *Hypothyroidism:* This has been associated with the development of OSAHS;[19] however, evidence indicates that the prevalence of hypothyroidism in

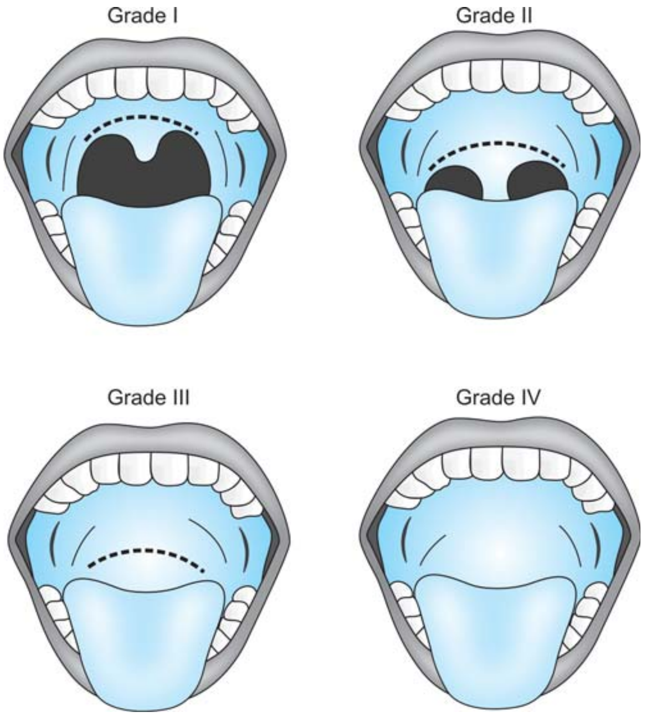

Fig. 129A.3: Grading of tonsil enlargement

TABLE 129A.1: Known risk factors for OSAHS

- Obesity
- Male sex
- Age
- Adenotonsillar hypertrophy, particularly in children and young adults
- Alcohol use
- Craniofacial skeletal abnormalities, particularly in nonobese adults and children
- *Family history:* Risk increases with each additional close family relative with OSAHS.[18]

patients with OSAHS is no higher than in the general population, therefore, patients with OSAHS need not be routinely screened for hypothyroidism, except possibly for the elderly women.

- Neurologic syndromes such as postpolio syndrome, muscular dystrophies, and autonomic failure syndromes such as Shy-Drager syndrome.
- *Stroke:* The relationship of OSAHS to cerebrovascular disease is still being determined. There is growing evidence that the prevalence of OSAHS is increased in patients who have had a stroke. However, whether OSAHS is a risk factor for stroke or stroke is a risk factor for developing OSAHS remains unclear.
- Acromegaly.

Laboratory Investigations

In addition to the routine clinical, radiological, hematological and biochemical assessments, investigations are required to establish the diagnosis and exclude other comorbidities and/or complications. Thyroid function tests should be performed on any patient with possible obstructive sleep apnea-hypopnea syndrome who has other signs or symptoms of hypothyroidism.

An arterial blood gas determination is needed in patients presenting with cor pulmonale, in order to rule out daytime hypoxemia or hypercapnia. Pulmonary function tests should be performed if the patient has evidence of cor pulmonale or if nocturnal symptoms are suggestive of nocturnal asthma (patient wakes up with shortness of breath that does not immediately resolve or is associated with wheezing).

An overnight sleep study or polysomnography is required to diagnose obstructive sleep apnea-hypopnea syndrome. During polysomnography, multiple body functions are monitored in asleep patient (Fig. 129A.4). Guidelines for the indications and performance of polysomnography are now available which include the following[20] (Figs 129A.5A to C):

- Sleep stages are recorded via an electroencephalogram, electrooculogram and chin electromyogram.
- Heart rhythm is monitored with a single-lead ECG.
- Leg movements are recorded via an anterior tibialis electromyogram.

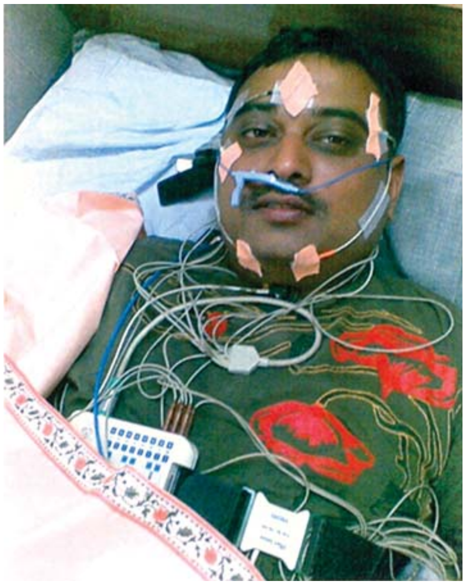

Fig. 129A.4: Shows the patient with all the sensors and recorder during polysomnography in sleep laboratory

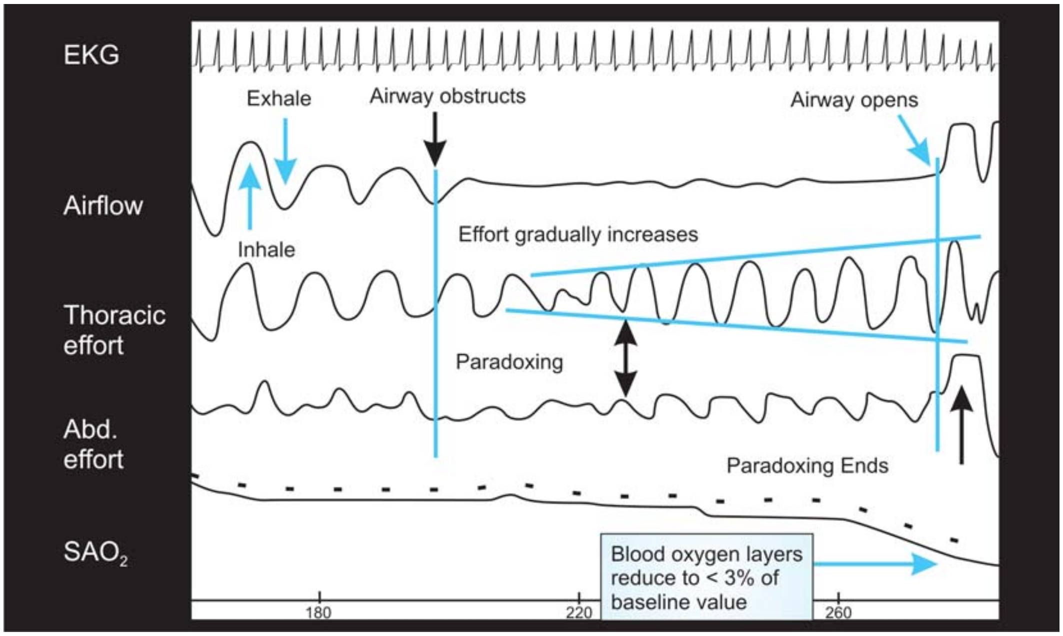

Fig. 129A.5A: Obstructive sleep apnea. Note the absence of flow despite paradoxical respiratory effort (blue arrows)

- Breathing is monitored, including airflow at the nose and mouth (using both a thermal sensors and a nasal pressure transducer), effort (using inductance plethysmography), and oxygen saturation.
- The breathing pattern is analyzed, for the presence of apneas and hypopneas. Definitions have been standardized by the American Academy of Sleep Medicine (AASM).[21]

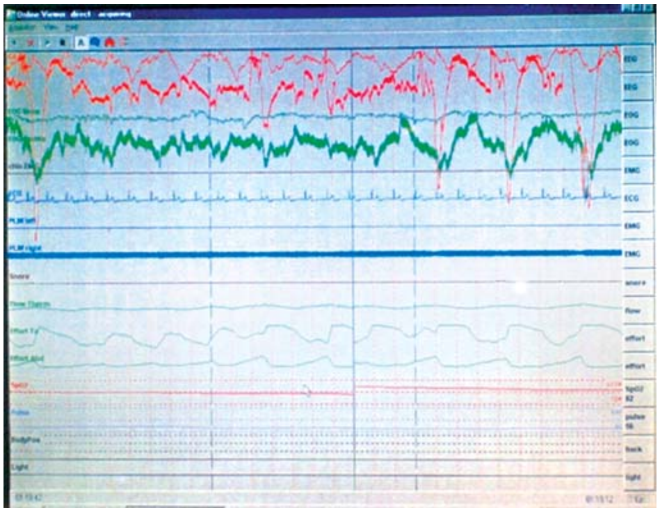

Fig. 129A.5B: All parameters during running polysomnography

- Obstructive apnea is the cessation of airflow for at least 10 seconds with persistent respiratory effort (Fig. 129A.6).
- Central apnea is the cessation of airflow for at least 10 seconds with no respiratory effort (Fig. 129A.6).
- Mixed apnea is an apnea that begins as a central apnea and ends as an obstructive apnea (Fig. 129A.7).
- The recommended definition of hypopnea is a 30% or greater decrease in flow lasting at least 10 seconds and associated with a 4% or greater oxyhemoglobin desaturation (Fig. 129A.8). An alternative definition is a 50% or greater reduction in flow lasting at least 10 seconds and associated with either a 3% or greater oxyhemoglobin desaturation or an arousal.
- Respiratory event-related arousal is an event in which the patient has a series of breaths with increasing respiratory effort or flattening of the nasal pressure waveform leading to an arousal from sleep that does not otherwise meet the criteria for an apnea or hypopnea.
- The AHI (apnea-hypopnea index) is derived from the total number of apneas and hypopneas divided by the total sleep time.
- A normal cutoff for AHI has never been defined in an epidemiological study of healthy people. Most sleep centers use a cutoff of 5–10 episodes per hour.[10]

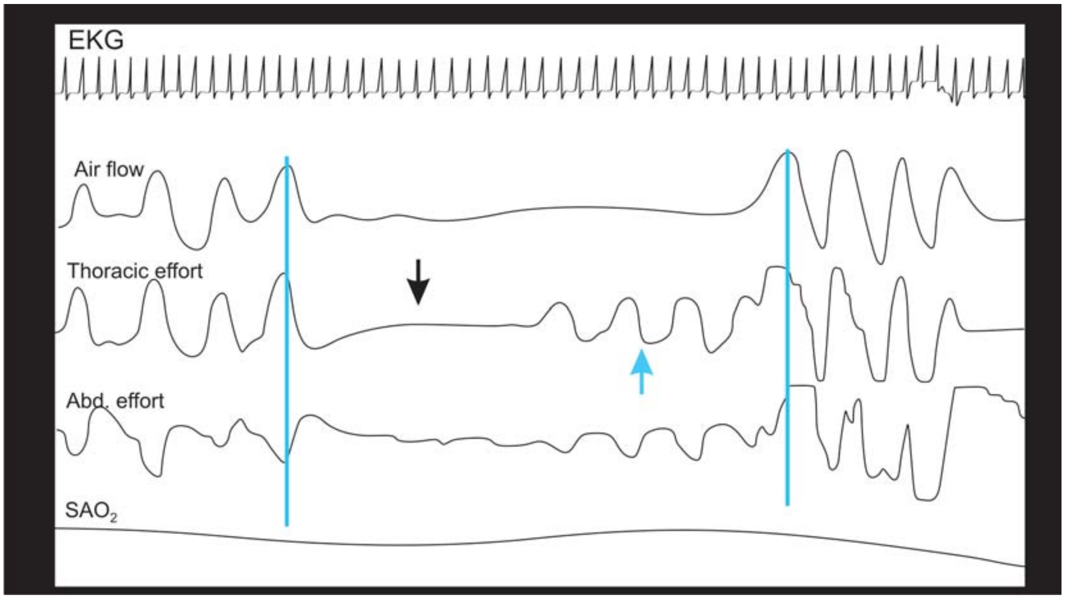

Fig. 129A.7: Mixed apnea, a complete absence of nasal and air flow. A total absence of respiratory effort at the beginning of the event (black thick arrow) is followed by gradual increase in effort (blue thick arrow) which eventually breaks the apnea. An oxygen desaturation is ≥3%

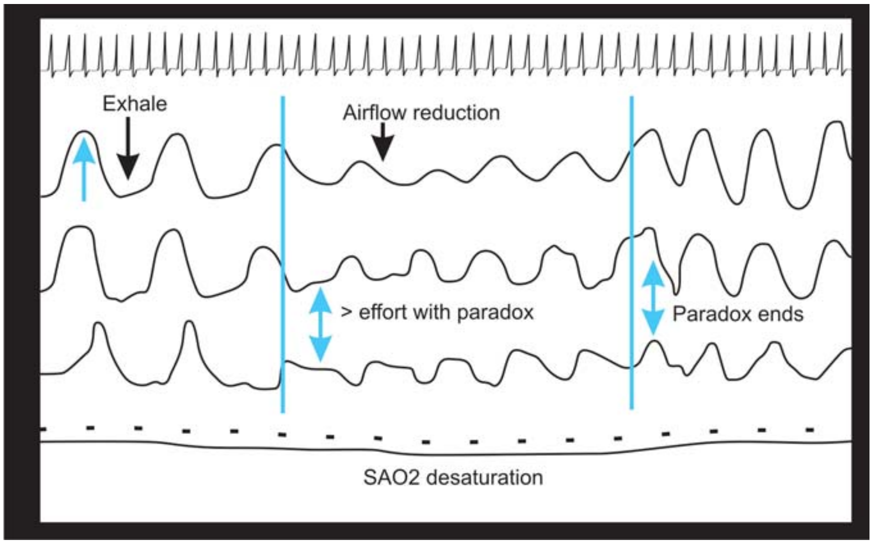

Fig. 129A.8: Hypopnea. This is an 18 sec hypopnea event. The airflow signal is reduced by 50% during this event (small black arrow)

- The severity of OSAHS is arbitrarily defined and differs widely between centers. Recommendations for cutoff levels on AHI include 5–15 episodes per hour for mild, 15–30 episodes per hour for moderate and more than 30 episodes per hour for severe.

The use of portable monitors for the in-home diagnosis of OSAHS is becoming more common. The American Academy of Sleep Medicine has published guidelines on the use of portable monitors. These guidelines recommend its use only in patients with a high probability of disease and in those without comorbidities (particularly congestive heart failure), and that negative studies be followed by a full, attended study.[21]

Polysomnography can be followed by a MSLT. The MSLT is considered an objective measurement of EDS. The MSLT consists of 4–5 naps of 20-minute duration every two hours during the day. The latency to sleep onset for each nap is averaged to determine the daytime sleep latency. Normal daytime sleep latency is greater than 10–15 minutes. OSAHS is generally associated with latencies of less than 10 minutes. The routine use of the MSLT in the evaluation of OSAHS has significantly decreased because sleep physicians generally treat OSAHS based on the subjective symptoms reported by the patient. The MSLT is generally used to confirm the diagnosis of narcolepsy in patients in whom narcolepsy is a consideration. As opposed to people without narcolepsy, narcoleptic patients have rapid eye movement sleep on at least two of the 4–5 naps during the day.

Treatment

The treatment of obstructive sleep apnea-hypopnea syndrome in part depends on the severity of the sleep-disordered breathing. People with mild apnea have a wider variety of options, while people with moderate-to-severe apnea should be treated with nasal CPAP.

Conservative measures include weight loss, avoidance of alcohol for 4–6 hours prior to bedtime and sleeping on one's side rather than on the stomach or back. These measures are included in the treatment of all patients with OSAHS, but uses as primary treatment in patients with very mild apnea whose main symptom is snoring. In a 2006 practice parameter, both weight loss and positional therapy were rated as "guidelines," indicating a patient care strategy with a moderate degree of evidence.[22]

Nasal Continuous Positive Airway Pressure (CPAP)

CPAP is the most effective treatment for OSAHS, and has become the standard of care. CPAP works by splinting the upper airway, and preventing the soft tissues from collapsing (Figs 129A.9A and B). By this mechanism, it effectively eliminates the apneas and/or hypopneas, decreases the arousals and normalizes the oxygen saturation.

Most sleep center physicians still titrates the CPAP level during a sleep study. This can be done on the second night of the study or during the second half of the diagnostic study, termed a split-night polysomnography. Guidelines for positive-pressure titration studies are available.[23-25]

Currently, CPAP devices are available that automatically change pressures based on the presence and/or absence of OSAHS (auto-positive airway pressure, or auto-PAP), where the need of titration is not required. The rationale for auto-titrating devices is based on the concept that the pressure required to treat OSAHS may vary over the course of the night and between different nights, sleep stages, and body positions with

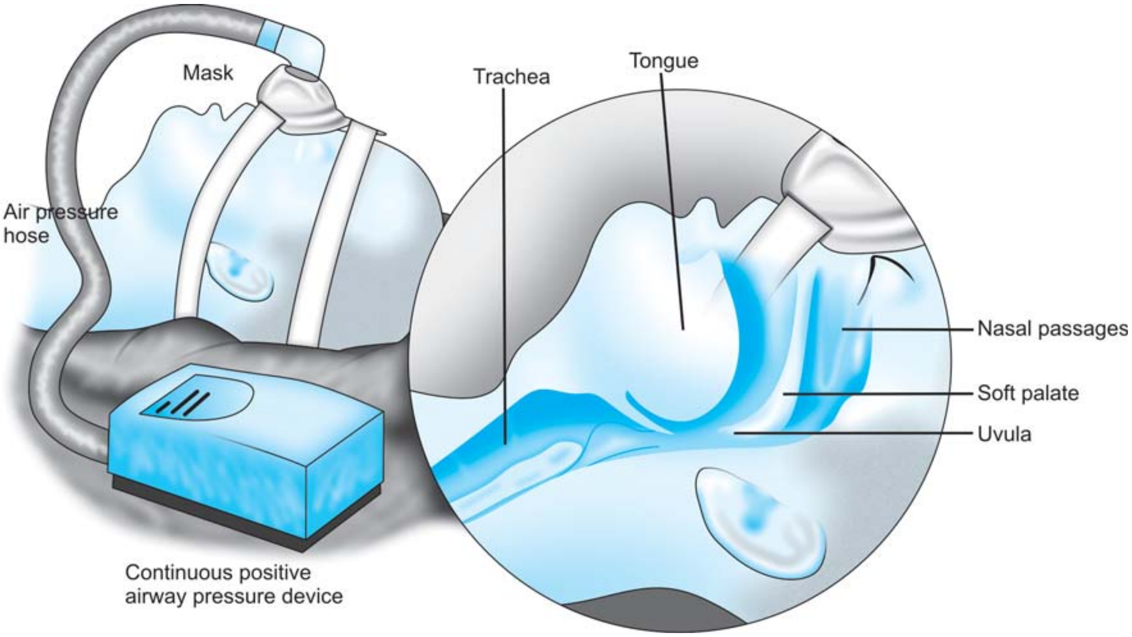

Fig. 129A.9A: CPAP device along with patient is seen. Left side shows the CPAP equipment with air flowing with supra-atmospheric pressure through the Air Pressure Hose and delivered to the patient through nasal mask (part of figure outside the circle). The continuous positive pressure acts as an air splint and keeps the closed airway during apnea as opened (part of figure in circle)

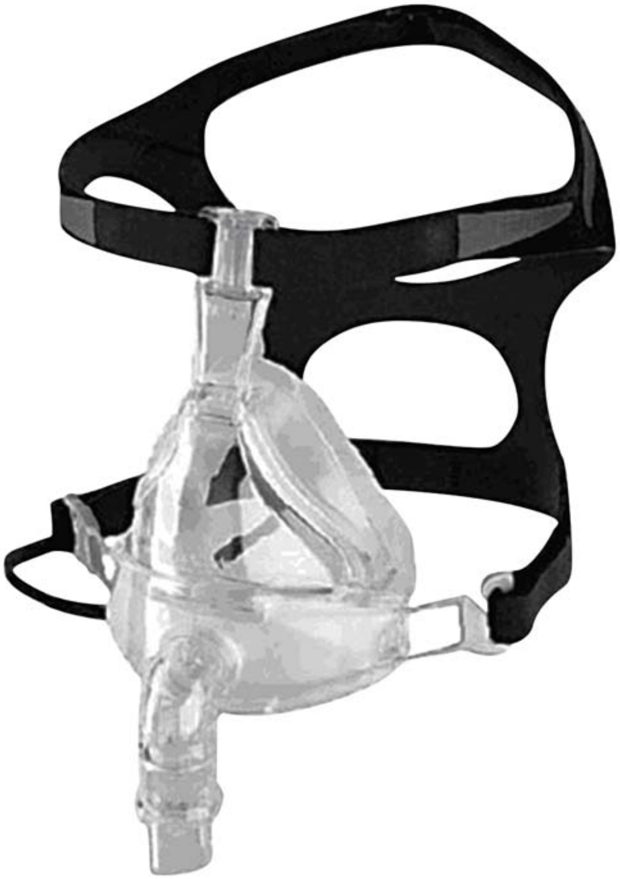

Fig. 129A.9B: Shows the nasal mask along with head gear. Latter keeps the mask tightened on the nose to prevent any air leak

the variations not captured by a one-night titration study. In theory, the mean pressure delivered by auto-PAP devices is lower than that delivered with fixed CPAP; however, no studies have shown increased patient compliance with auto-PAP devices.[26]

All patients with an AHI greater than 15 are considered eligible for CPAP, regardless of the symptomatology. For patients with an AHI of 5–14.9, CPAP is indicated only if the patient has one EDS or comorbidities (hypertension, cardiovascular disease or combination of them).

Continuous positive airway pressure has been shown to improve daytime sleepiness, mood, and cognitive function in people with both mild and moderate apnea.[27,28] It has also been shown to increase quality of life.[29.] Continuous positive airway pressure decreases blood pressure, primarily in patients with severe OSAHS, and may improve the left ventricular ejection fraction in patients with congestive heart failure and OSAHS.[30]

The most common adverse effects of CPAP are dry mouth, rhinitis and sinus congestion. These can be treated effectively with humidification and antihistamines and/or nasal steroids.

Many patients do not accept (or even initiate) CPAP therapy and up to 25% do not regularly follow-up with a sleep physician;[31] most of these patients are nonadherent to therapy. Continous positive airway pressure compliance may be determined as early as two weeks after CPAP is initiated. Patients who consistently use their positive airway pressure device at six months were, on an average using the device for more than 2 hours per night during the first two weeks, were more ready and confident to continue use. On the other hand, intermittent users were more likely to report general discomfort and adverse effects from the device, and that the device was too inconvenient. Compliance can be objectively measured.[32] Most modern positive airway pressure machines measure both “machine-on” and “mask-on” times, with the mask-on time used to measure compliance.

Some patients require the use of bi-level positive airway pressure (BiPAP). In BiPAP, a higher inspiratory pressure and a lower expiratory pressure are used. In patients with sleep apnea, the levels are set such that the expiratory pressure eliminates apneas and the inspiratory pressure eliminates hypopneas. BiPAP is generally used in patients who cannot tolerate high CPAP pressures (patients who experience difficult exhalations) or who have barotrauma complications (ear infections, bloating). Many physicians automatically place a patient on BiPAP if the CPAP level needs an increase above 15 cm water. Compliance with BiPAP has not been demonstrated to be better than the compliance with CPAP.[33]

Follow-up of Patients on CPAP Therapy

Once diagnosed with OSAHS and started on nasal CPAP, patients require regular follow-up with a sleep specialist. Most patients are seen within two months of initiating CPAP to determine if it has been effective in alleviating symptoms, to troubleshoot problems preventing the regular use of the CPAP, and to reinforce the importance of daily use. Further follow-up depends on whether the CPAP has been effective.

- If effective, the patient is generally seen at 6–12 month intervals to troubleshoot new problems, to reinforce daily use and to be certain the CPAP remains effective.
- If CPAP has not been effective, problems preventing use are identified, steps are taken to eliminate problems and the patient is seen at 2–3 month intervals until the use is regular and the CPAP is effective in alleviating symptoms. Repeat titration may be necessary.

- Routine repeat polysomnography is generally not indicated for patients who report improved symptoms. Repeat CPAP titrations are usually performed in patients without effective relief of their symptoms despite intervention or in patients who had relief of symptoms but present months to years later, reporting the return of symptoms, generally in association with weight gain.
- Residual EDS after treatment with CPAP is a commonly encountered problem.

Oral Appliances

These devices act by moving the tongue or mandible forward, thereby enlarging the posterior airspace (Figs 129A.10A and B). Multiple different devices are available. In 2006, the AASM published practice parameters and a review of the use of oral appliances in persons with OSAHS.[34,35]

Multiple small cohort studies have shown that these devices effectively lower the AHI in case of: Mild-to-moderate disease (AHI <30); lower BMI; increased mandibular protrusion with the device; and the presence of positional OSAHS. Guidelines recommend that oral appliances are indicated for patients with mild-to-moderate OSAHS who prefer oral appliances to CPAP devices; patients with mild-to-moderate OSAHS who do not respond to CPAP therapy; and patients with mild-to-moderate OSAHS in whom treatment attempts with CPAP devices fail. Oral appliances should not be considered effective therapy for patients with severe OSAHS.

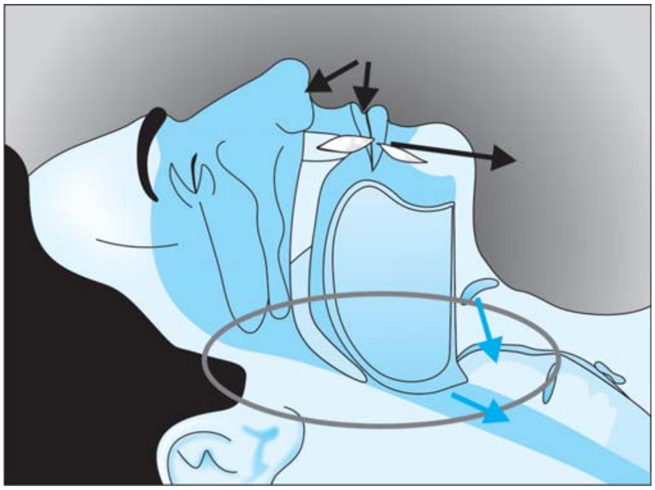

Fig. 129.10A: Shows the relaxed jaw position to cause tongue and throat tissue to collapse and narrow the airway (blue arrow)

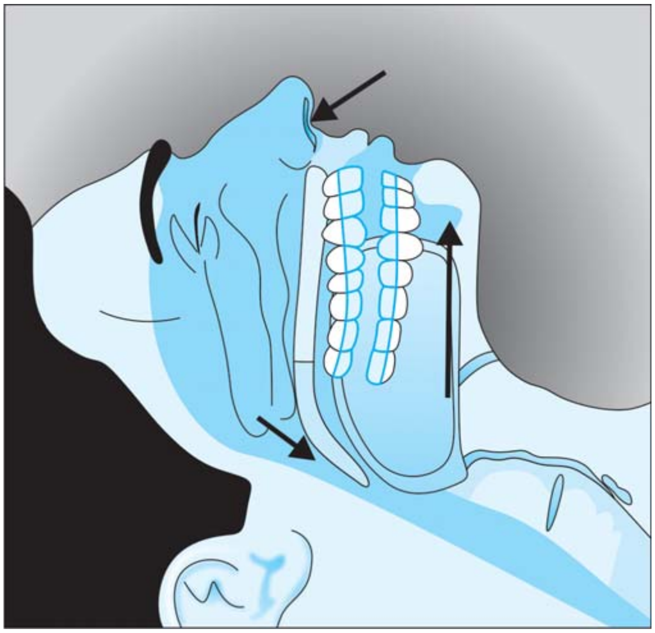

Fig. 129.10B: Shows the oral TAP (Thornton Adjustable Positioner) device that is worn over the teeth, much like an athletic mouth guard. The device gently moves the lower jaw slightly forward, opening airway (arrows) and improving nighttime breathing and alleviating snoring

Surgical Treatment

Surgical correction of the upper airway is still performed but is not considered primary therapy for OSAHS. The theoretic advantage of surgery if the patient is cured is that, compliance with CPAP or an oral appliance is no longer an issue. However, a primary reason that surgery has not become a standard therapy is the lack of long-term outcome studies that show that the surgical correction continues to be effective for five or more years after it is performed.

Factors that increase the likelihood of successful surgery include lower AHI, lower BMI, the location of collapse (surgeries targeted specifically to collapse at either the nasopharynx or oropharynx improve outcome), the degree of mandibular protrusion (better outcomes are achieved in patients with clear deficiencies), and the presence of fewer comorbidities.

Patients should be considered for surgery primarily if multiple attempts at therapy with CPAP have failed and if an oral appliance is not an option. If the patient opts for surgery, ensure that it should be performed by a qualified surgeon and the patient should be willing to undergo combination or multiple surgeries. Guidelines for the surgical treatment of OSAHS were last published in 1995.[36] Surgery procedures include the following:

- Uvulopalatopharyngoplasty (UPPP, Figs 129A.11A and B) is the resection of the uvula and soft palate. It is effective in approximately 40% of patients, but predicting which patients will benefit from the procedure, is problematic. Patients with treatment success often present with a recurrence of symptoms, especially if they continue to gain weight.
- Craniofacial reconstruction involves advancement of the tongue [geniohyoid advancement with hyoid myotomy (GAHM) or maxillomandibular bones osteotomy (MMO)]. These procedures should be performed only at centers with expert personnel. Short-term success rates are approximately 70% for GAHM and 95% for MMO. No good long-term studies have been performed to evaluate the success for either GAHM or MMO.
- Tracheostomy provides definitive correction because it bypasses the obstruction. It is recommended for patients with very severe OSAHS, especially if the patient does not tolerate CPAP or has cor pulmonale. In author's experience, the patients in India do not opt for tracheostomy.
- Bariatric surgery as therapy for OSAHS has been investigated in several nonrandomized, uncontrolled studies, with most showing a decrease in the AHI with weight loss. The 2006 practice parameter on medical therapies for OSAHS lists bariatric surgery as an option for OSAHS, although with limited evidence.[26]

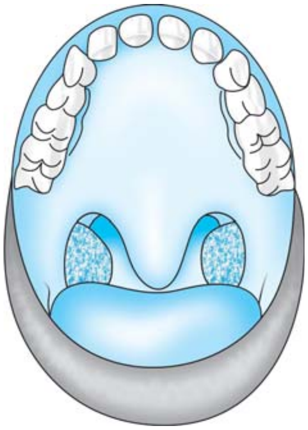

Fig. 129A.11A: Shows the oral cavity with narrow air space before UPPP

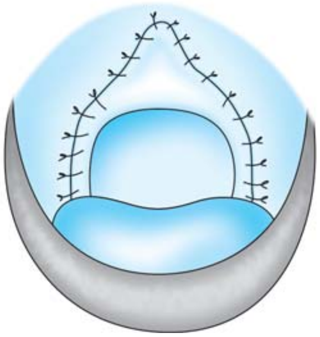

Fig. 129A.11B: Shows the oral cavity with widened air space following UPPP

Follow-up of Patient with Surgery/Oral Devices

If a patient chooses upper airway surgery or an oral appliance, he or she requires repeat polysomnography after surgery or with the device in place to be sure the OSAHS has improved.

Diet: All patients who are obese, should be counseled about the importance of diet and exercise, should be referred to a dietitian and/or a weight loss program.

Drug Therapy: The drugs have been used with no demonstrable effect. The AASM recently published a practice parameter and review of the medical therapies of OSAHS.

- Use of protriptyline for OSAHS was listed as a guideline (patient care strategy based on level 2 or 3 evidence).[37]
- The use of modafinil is recommended for the treatment of residual sleepiness in persons with OSAHS, is considered a standard treatment (generally accepted patient care strategy with level 1 or excellent level 2 evidence).
- Selective serotonin reuptake inhibitors, methylxanthines and estrogen replacement therapy should not be considered for the treatment of OSAHS.
- Central nervous system stimulants, nonamphetamine are used for treatment of fatigue without interfering with normal sleep architecture. They promote wakefulness.
- Concern exists that the use of modafinil (or other stimulants) in the management of OSAHS may result in decreased CPAP usage. This is important because stimulants do not control the sleep-disordered breathing, resulting in worsening symptom control and potentially increasing the risk of cardiovascular morbidity. The dose of modafil used is 100–200 mg PO qd; some patients may require as much as 300 mg PO qd. This is not recommended for children.

Prognosis

The short-term prognosis, in relation to symptoms such as daytime sleepiness and snoring, ranges from good to excellent with regular use of CPAP. The long-term prognosis is unknown because no randomized treatment studies investigating the effect of CPAP on preventing the development of cardiovascular squeal have been conducted.

Patient Education

All patients with obstructive sleep apnea-hypopnea syndrome should receive education about sleep and proper sleep hygiene, OSAHS, and the risks of driving while sleepy. They also should receive education regarding the role of nasal CPAP and the importance of its daily use.

Special Concerns

Motor Vehicle Accident Risk

Predicting accident risk in patients with obstructive sleep apnea-hypopnea syndrome is difficult because many individuals with OSAHS do not accurately perceive their level of drowsiness. A large body of work has been compiled on the influence of OSAHS on driving-simulator performance, with the majority of the studies indicating poor performance, similar to that seen with alcohol impairment while driving.[38] The regular use of CPAP improves the driving performance. At least two studies have shown improvement on a driving simulator after CPAP use.[39,40] Specifically, in one study, the number of off-road events decreased from 17.8 to 9 after one month of effective CPAP therapy, but no change was noted after a month of ineffective pressure set at 1 cm H_2O.

Geriatric Populations

The prevalence of OSAHS increases with age. However, the clinical significance of OSAHS in healthy, community-dwelling people has been questioned because these people do not show significant squeal (sleepiness). Elderly patients presenting to sleep centers for evaluation have similar symptomatology (including EDS) and polysomnographic results compared with patients who are not elderly, except that elderly patients under report snoring as a chief complaint, they tend to be less obese and they are less objectively sleepy based on MSLT results. Thus, all elderly people, particularly if overweight, should be questioned about snoring, witnessed apneas and daytime sleepiness and should be referred for evaluation if necessary. Age does not appear to influence compliance to CPAP therapy. Thus, all elderly patients with significant and symptomatic OSAHS should be offered therapy.

Pediatric Populations

OSAHS in children has an estimated prevalence of 2%, affecting boys and girls in equal numbers. Children most often present with loud snoring and symptoms and signs of adenotonsillar hypertrophy. EDS is not a common symptom in children with OSAHS. Instead, school-aged children often report problems with schoolwork. Studies have shown improvement in cognitive function and/or grades after adenotonsillectomy in children with OSAHS.[41]

Pregnancy

Several case reports associate intrauterine growth restriction (also termed intrauterine growth retardation) in pregnant women with concomitant untreated OSAHS. Complications such as hypertension, preeclampsia, low Apgar scores and intrauterine growth restriction were more common in habitually snoring pregnant women compared with nonsnoring pregnant women.[42] Habitual snoring was independently predictive of hypertension and growth restriction after correcting for other factors (weight, age, smoking status).

Obstructive Sleep Apnea

Macy MS Lui, Mary SM Ip

INTRODUCTION

Sleep-related breathing disorders have become a mainstream topic in clinical medicine in recent decades, when epidemiological studies clearly demonstrated the common occurrence of sleep apnea in various ethnic populations. With the growing recognition of the importance of Obstructive Sleep Apnea (OSA), research has been blooming to uncover its pathophysiology, neurobehavioral and cardiometabolic consequences, as well as effective therapeutic modalities.

EPIDEMIOLOGY AND RISK FACTORS

Obstructive sleep apnea is characterized by intermittent upper airway collapse during sleep, resulting in recurrent bouts of hypoxia and arousals. Obstructive Sleep Apnea Syndrome (OSAS) refers to the clinical manifestations, often excessive sleepiness, in the presence of significant OSA. Various prevalence studies have been undertaken across the continents and the reported prevalence rates range from 3 to 50%, indicating that it is a common disorder affecting worldwide populations (Table 129B.1). The heterogeneous rates can be explained by the highly diverse study populations of different ethnicity, age and cultural background, and the different study design or methodology, including diagnostic tools and event definitions. The rising body mass index surely contributes to the higher prevalence reported in the more recent studies and thus the figures quoted from studies done in 1990s are likely to be substantially underestimating the real time prevalence currently.

Age and Sex

Numerous studies support the increasing occurrence of OSA with advancing age and this plateaus after the age of 65.[1] In women, the prevalence of OSA starts to rise after menopause.

Obstructive sleep apnea has also been consistently found to be more common in men, with male:female ratios reported to range from 2:1 to 8:1. The male:female ratios with OSA in clinic-based studies appear to be considerably higher than in the community (approximately 5:1 to 8:1 versus 2:1 to 3:1).[2] The reasons for the gender difference in OSA prevalence have not been clearly defined, but the discrepancy of community versus clinic ratios suggest that women with OSA may present less than their male counterparts for clinical consultations. Although the exact underlying reasons for the under presentation of women have not been investigated, it is likely the situation would be worse in developing countries where access to medical facilities are limited and in some communities, where cultural perceptions may favor men as the priority gender in health care.

Body Habitus

The epidemic of obesity is sweeping worldwide and the impact is no less in the developing countries in concert with economic development, increased urbanization and increased consumption of high-calorie food. The prevalence of obesity ranges from 20 to 50% in recent studies, including mainly urban Indians and similarly high figures are also reported in many other developing countries.[3] Obesity is considered a major risk factor of

TABLE 129B.1: Prevalence studies of OSA in adults

Author/ year	*Subjects undergoing PSG/diagnostic tool*	*Age (Yrs)*	*BMI (kg/m²)*	*Findings*
Tufik et al. 2010[4]	1042 community dwelling Brazilian, by PSG	20 t0 80	64% had BMI ≥30	Prevalence of OSAS was 41% in men, 26% in women
Johansson et al. 2009[5]	331 community dwelling elderly in Sweden, by PSG	71 to 87	Mean ~27	55% with OSA (AHI ≥5), half of them had moderate-severe OSA
Reddy et al. 2009[6]	Q: 2505 community dwelling urban Indian PSG: 365	30 to 65	24.3 ± 4.6	Estimated population prevalences of OSA and OSAS were 9.3% and 2.8%, respectively
Sharma et al. 2006[7]	Q: 2150 semi-urban population in Delhi PSG: 150	30 to 60	24.6 ± 5.2	Prevalences of OSA and OSAS were 19.7% and 4.9% in men, 7.4% and 2.1% in women, respectively
Udwadia ZF et al.[8]	Q: 658 healthy urban Indian men 250 underwent home sleep study	35 to 65	24.6 ± 4.3	Estimated prevalence of OSA 19.5%, OSAS 7.5%
Ip et al. 2004[9]	Q: 854 community dwelling women in Hong Kong PSG: 106	30 to 60	22.4 ± 3.2	Conservatively estimated prevalence of OSA (AHI ≥5) were 3.7%; OSAS 2.1%
Ip et al. 2001[10]	Q: 784 community dwelling men in Hong Kong PSG: 153	30 to 60	23.9 ± 3.5	Conservatively estimated prevalences of OSA (AHI ≥5) were 8.8%; OSAS 4.1% Bixler EO
et al.[11]	Q: 12219 Caucasian women, 4364 Caucasian men PSG: 1000 women, 741 men	20 to 100	29.6 ± 7.5(women) 26.9 ± 4.2(men)	Prevalences of sleep disordered breathing (AHI ≥10 and daytime symptoms) were 3.9% in men, 1.2% in women
Ng et al. 1998[12]	2298 multi-ethnics in Singapore, by survey and symptoms criteria	40 to 59	24.0 (95% CI 23.6–24.4)	Prevalence of snoring: 6.8% (whole population), 6.2% (Chinese), 8.1% (Malay), 10.9% (Indian) OSA: 0.43% (whole population)
Ohayon et al. 1997[13]	Telephone interview survey: 2078 men, 2894 women	15 to 100	Not available	OSAS: 3.5% in men and 1.5% in women
Marin et al. 1997[14]	1222 community dwelling Spanish, 50% men, by night oximetry	18 to 88	About 24	Overall 11% had >10 desaturations/hour. OSAS in 3% men and 1.7% women
Olson et al. 1995[15]	441 community dwelling Australians, by PSG	35 to 69	Not available	Moderate OSA (AHI ≥15) was present in at least 5.7% men, and 1.2% women
Young et al. 1993[16]	Q: 3515 state employees in Wisconsin, USA PSG: 602	30 to 60	About 30	OSA (AHI ≥5): 24% in men, 9% in women OSAS: 4% in men, 2% in women

AHI = Apnea Hypopnea Index
OSA = Obstructive Sleep Apnea
OSAS = Obstructive Sleep Apnea Syndrome (OSA in the presence of excessive sleepiness)

OSA across various ethnic populations.[17] In a population-based cohort study in USA, a 10% weight gain predicted an approximate 32% increase in the AHI while a 10% weight loss predicted a 26% decrease in the AHI.[18] A similar trend was also observed in pediatric population.[19] Adipose tissue deposited around the upper airway reduces the airway size and increase its collapsibility, thus increasing neck circumference also predicts OSA.[20] Truncal obesity could adversely affect the ventilatory mechanic by reducing the functional residual capacity, increasing the chest compliance and work of breathing, and decreasing the efficiency of the compensatory mechanism in the body in face of hypoxemia or hypoventilation.[21]

Craniofacial Factor

Craniofacial structure comprises of bony component and soft tissue component. Bony factors are believed to be more important factor predisposing to OSA in lean subjects, both bony and soft tissue factors contributed in moderately obese subjects and the acromegalics, while soft tissue abnormalities dominate in obese or hypothyroid subjects.[22-24] Reversible sleep disorder breathing is common among subjects with primary hypothyroidism.[25] Cephalometric abnormalities have been described in a number of Caucasian as well as Asian studies, reduced dimension of anterior cranial base, reduced posterior and superior airway spaces, inferiorly displaced hyoid, increased soft palate dimension, other soft tissue enlargement were identified as the risk factors for OSA.[26-28] Other commonly described features include retrognathia and enlarged tongue. In addition to BMI and age, larger thyromental angle, higher Mallampati score, increased neck circumference were demonstrated to be predictors of OSA in both Chinese and Caucasian adults.[29]

Genetic Influence

Subjects with first degree relatives affected by OSA are noted to present at a younger age with snoring, with lower BMI, and smaller posterior airway space than their nonfamilial counterparts.[30] Genetic makeup and a number of the craniofacial syndromes determine the craniofacial morphology and the neuroventilatory mechanism governing the collapsibility and caliber of the upper airway, which directly predispose to OSA. The Angiotensin-converting enzyme gene insertion/deletion polymorphism was significantly associated with hypertension in OSA subjects.[31] Apolipoprotein E (APOE) is found in chylomicron and is essential for normal catabolism of triglyceride-containing lipoproteins.[32] The presence of dysfunctional APOE product, ApoE-ε4, was associated with higher risk of moderate to severe sleep disordered breathing, regardless of age, sex, BMI and ethnicity.[33] Apolipoprotein E4 was also linked to neurocognitive deficits in OSA.[34,35]

Ethnicity

Ethnicity may influence genetic, cultural or environmental factors, all of which could predispose to OSA. Craniofacial features differ across ethnicities, as well as the prevalence of obesity, which is heavily affected by socioeconomic environment in addition to genetic influence. Socioeconomic status also affects diet and exercise habits, access to health care and levels of health awareness, which could all influence the prevalence of OSA. In developing countries, even when the population is of the same ethnicity, continuing under-nutrition in the less developed areas and escalating over-nutrition associated with urbanization and economic development in other areas, have created double jeopardy to the health care systems.[16] Cultural differences could pose influence in perception, acceptance and threshold for reporting sleep complaints. European-Americans were found to report more sleep-related symptoms than other ethnic groups in a population-based studies, including 1,118 older adults in New York.[36] Among Caucasian and Asian adults matched for age, sex and BMI, there was no difference in the severity of reported symptoms, despite the significantly higher Respiratory Disturbance Index (RDI) and lower oxygen saturation in Asian adults.[37] It was plausible that Asian was more tolerant of the OSA symptoms with a tendency for late presentation.

Other Risk Factors

Smoking and alcohol consumption have been reported to be risk factors for OSA.[38] Both allergic and nonallergic rhinitis were shown to predispose to OSA in previous studies.[39]

PATHOGENESIS OF OSA

The pathophysiological mechanisms predisposing to OSA involve a complex interplay of multiple structural and functional factors, each of variable degree of significance in an individual. The pharynx can be viewed as a collapsible conduit that comprises of muscles, which serves the functions of speech, swallowing and respiration. It is prone to occlusion when the surrounding pressure is greater than the intraluminal pressure. Anatomical structures, such as redundant soft tissue or bony structures are factors that increase the collapsibility of the upper airway. Pharyngeal Critical Pressure (Pcrit) is the extraluminal pressure at which maximal inspiratory flow occurs. It provides an objective surrogate measure of the collapsibility of upper airway in human. It is measured by lowering the nasal pressure until the inspiratory airflow ceases. Pharyngeal Critical Pressure defines a spectrum of severity of upper airway obstruction from normal breathing (Pcrit <-10 cm H_2O) to snoring (Pcrit -10 to -5 cm H_2O), to obstructive hypopnea (Pcrit -5 to 0 cm H_2O) and obstructive apnea (Pcrit > 0 cm H_2O) during sleep.[40,41] Patients with the Upper Airway Resistance Syndrome (UARS), characterized by inspiratory flow limitation and respiratory effort-related arousals, typically have Pcrit levels that are between snoring and hypopnea.[42]

Upper airway patency is sustained throughout the respiratory cycle by both tonic activity (e.g. Tensor palatini) and phasic activity (e.g. Genioglossus) of pharyngeal muscles. The tones of the pharyngeal muscles are regulated by conscious states-related mechanisms, local mechanoreceptor reflexes and central ventilator control mechanisms. In face of a narrowed airway, elevated neuromuscular activities of the pharyngeal muscles, mediated by pressure sensing mechanism and negative pressure reflex, are observed as compensatory mechanism to sustain airway patency.[43] There are evidence that such local neuromuscular compensation is impaired in patients with OSA.[41]

Ventilatory control mechanisms influence the pharyngeal collapsibility during sleep. The central nervous system is affected by signals from central and peripheral chemoreceptors responding to hypercapnia or hypoxemia, and increases ventilatory drive to upper airway and diaphragm in a coordinated manner. Increased hypercapnic ventilatory responses, prolonged circulatory times or low oxygen stores within the body can lead to ventilatory instability with subsequent periodic breathing.[44] Of note, measurement of loop gain, a measure of ventilatory instability, was shown to be high in patient with severe OSA.[45] Therefore, a brisk ventilatory response to hypoxemia/hypercapnia after an arousal in the susceptible individual can result in hypocapnia that reach the apnea threshold and result in a hypopnea or apnea with reinitiation of sleep.[46] Such self perpetuating cycle results in recurrent sleep apnea.

CLINICAL FEATURES

The classical symptoms for OSA include excessive daytime sleepiness (EDS) and habitual snoring. A range of other symptoms (Table 129B.2) have also been reported in association with OSA.

Excessive sleepiness is believed to be the result of sleep fragmentation and the repetitive hypoxic disturbance to the brain. The presence of EDS is usually assessed with the use of structured scales, such as the Epworth Sleepiness Scale (in this scale, a score of 10 out of maximum of 24 indicates excessive daytime sleepiness),[47] or more objectively by multiple sleep latency test and multiple wakefulness test. Subjective EDS correlates poorly with the presence and severity of OSA. It is also subject to many influences, such as cultural factors, personal threshold of tolerating sleepiness and social stigmatization at workplace. Excessive Daytime Sleepiness and lack of concentration at work could lead to tremendous loss in productivity and economic loss. A recent systemic review has confirmed that untreated OSA is a significant contributor to motor vehicle crashes and characteristics that may predict crash in driver with OSA include BMI, apnea hypopnea index, oxygen saturation and daytime sleepiness.[48] Other conditions associated with OSA could also contribute to the sleepiness, such as depression and hypothyroidism.

Patients may complain of insomnia, which includes difficulties in initiating sleep, recurrent awakening from sleep or early morning awakenings.[49] The bed partners may also notice the obstructive breathing pattern, which includes snoring, snorting, choking, witnessed apnea and restless sleep behavior due to recurrent arousals and some may be so disturbed that they sleep in a separate room.

Obstructive Sleep Apnea subjects also commonly have comorbidities, such as hypertension, diabetes mellitus, hyperlipidemia, atherosclerotic vascular diseases and the metabolic syndrome.[50] Physical examination would likely reveal an overweight or obese subject often with comorbid cardiometabolic diseases. (Table 129B.2)

In less developed places, people may only present for medical opinion when there are florid and disabling features, such as gross obesity or marked daytime sleepiness, but as socioeconomic status of the community

TABLE 129B.2: Symptoms and signs of OSA

Symptoms
- Heavy snoring
- Sleep choking
- Witnessed apnea
- Daytime sleepiness, history of motor vehicle accidents
- Poor concentration, poor memory
- Insomnia
- Nocturia
- Morning headache

Physical signs
- Overweight or obese, truncal obesity
- Crowded pharyngeal airspace
- Receding chin
- Macroglossia
- Tonsillar hyperplasia
- Elevated Mallampati score

Associated conditions
- Hypertension
- Stroke
- Diabetes mellitus
- Metabolic syndrome
- Hypothyroidism
- Acromegaly
- Allergic rhinitis
- Pulmonary hypertension

advances and public health care information increases, one will begin to see patients presenting with more equivocal symptoms. It is also important to note that a minority of OSA subjects are lean.

DIAGNOSIS

Risk Stratification for Referral for Polysomnography

Snoring and daytime sleepiness are the most common relevant presenting complaints in primary care. Snoring has been reported to be present in 18% of urban middle-aged Indians in a community-based study.[3] In the same study, 33.6% of the habitual snorers also complained of excessive daytime sleepiness. Clinical assessment using a combination of symptoms, physical examination findings and other objective tools, has been utilized to triage patients for PSG referrals, and this strategy is particularly important in resource limited settings.

Habitual snorers are at a higher risk of having OSA as compared to nonsnorers, but the positive and negative predictive values of snoring for the presence of OSA were 63% and 56%, respectively. Male gender, advanced age, higher BMI and abdominal obesity were identified to be the predictors of presence of OSA.[4] Higher Mallampati score, tonsillar hyperplasia and lateral pertitonsillar narrowing were associated with OSA independent of obesity.[51,52] Modified Berlin questionnaire, which classified patients into high or low risk categories according to clinical domains, including snoring, sleepiness, obesity and hypertension, was validated as screening tool for the presence of OSA.[53] High-risk category predicted an AHI>5 with a sensitivity of 86%, specificity 95%, positive and negative predictive values of 96% and 82%, respectively. However, the Berlin questionnaire had a low diagnostic accuracy for a predominantly Chinese population.[54] This might be attributed to the use of a BMI obesity threshold, which is meant for Caucasians.

Portable Monitoring

Sleep recording devices are classified into four types: Type 1 is standard in-laboratory attended PSG, type 2 uses the same technology as type 1 but is unattended, type 3 records 4 to 7 physiologic parameters and at a minimum include two respiratory parameters (airflow and effort), a cardiac signal (pulse or electrocardiogram), and oxygen saturation. Type 4 devices measure only one or two parameters, including oxygen saturation. Portable devices are becoming more sophisticated but lack standardization.

Portable monitoring is increasingly used as alternative approach to PSG for the diagnosis of OSA in some countries including USA, following the statement by the US Centers for Medicare and Medicaid Services in 2008.[55,56] The use of unattended portable devices is typically recommended in populations at high-risk for OSA clinically without significant comorbid medical conditions.[57] Overnight oximetry is occasionally used as screening tools for OSA but the reported sensitivity and specificity were suboptimal.[58] The finding of frequent oxygen saturation dips in the presence of appropriate clinical settings can support the diagnosis of OSA.

The interpretation of oximetry could be difficult in subjects with underlying pulmonary or cardiac disorders associated with hypoxia. Oximetry frequently underestimates the severity of sleep disordered breathing, as arousals are not measured. The mechanism of desaturation, with regard to obstructive, central or mixed apnea, is not discernible with the use of oximetry. Sleep disorders, such as upper airway resistance syndrome, periodic leg movement syndrome and narcolepsy may not be diagnosed by oximetry. Despite such shortcomings, unattended home sleep studies or split night polysomnography (PSG) were found to be cost-effective alternatives to PSG in resource-limited settings.[59]

Actigraphy is a specific portable device that record body activity and movement, which is interpreted by computer algorithm as sleep versus wake periods. It is useful for diagnosis of circadian rhythm sleep disorders, and when it is combined with a validated way of monitoring respiratory events, use of actigraphy may improve accuracy in assessing the severity of obstructive sleep apnea compared with using time in bed.[60]

Polysomnography

Overnight in-laboratory attended PSG is the standard test for diagnosis of OSA, which comprises of recordings of sleep stages (electroencephalogram, electrooculogram, submental electromyogram), respiratory events (airflow, thoracoabdominal effort, oximetry), cardiac rhythm (electrocardiogram) and other relevant signals (leg movement, snoring, video recording).[61] Despite the fact of being the gold-standard, the high cost and long waiting list of PSG makes it less readily available than portable monitoring. The interpretation of PSG recordings would be technically suboptimal if subjects could not sleep long enough in-laboratory (≥ 4 hours). This is sometimes called first night effect, which also contributes to the night-to-night variation of the PSG recordings. The reduced sleep duration or quality would pose problem in the accuracy of diagnosing sleep-related disorders mainly affecting Rapid Eye Movement sleep (e.g. OSA, REM-related sleep behavioral disorder), which predominate in later part of the night with deeper sleep.

The various sleep stages experienced by the patient and the oximeter tracings are summarized on the hypnogram. Respiratory events are classified into apnea, hypopnea or Respiratory Effort-Related Arousals (RERA), which could be central or obstructive in mechanism (Table 129B.3). Obstructive events occur with upper airway partial/complete obstruction in the presence of respiratory effort, while no respiratory effort is found in purely central events. Definition of RERA varies across centers and it is commonly accepted to indicate a sequence of breaths over the duration of at least 10s with increasing respiratory effort, which results in an arousal. Respiratory Effort Related Arousals (RERAs) may not involve any oxygen desaturation and constitute the main events in the entity called Upper Aiway Resistance Syndrome (UARS), which is believed to be part of OSA disease spectrum with similar pathophysiology and clinical consequences. Apnea Hypopnea Index (AHI), the number of apnea or hypopnea per hour of sleep, is the most commonly used parameter to indicate severity of OSA. Respiratory Disturbance Index (RDI) refers to the sum of AHI and RERA.

Pragmatic Approach to Diagnosis in Developing Countries

The diagnosis of OSA carries important long-term therapeutic implications and therefore, one must attempt a reliable diagnosis within resource constraints.

In developed countries, full overnight polysomnography in the sleep laboratory is considered the gold standard, but this may not be applicable to developing economies. And even in well developed health care systems, there is a revisit to the diagnostic algorithm as there is an overwhelming demand with a long waiting list for sleep studies due to the escalating prevalence of obesity and OSA.[62]

For those presenting with typical OSA symptoms with no comorbidities to cause nocturnal desaturation, a combination of questionnaire (which may need local adaptation and validation) and limited sleep study may suffice, with further referrals for full sleep studies in those with significant symptoms but no definitive diagnosis.[63,64]

If one is suspecting other types of sleep apnea, there is a need of tests with more respiratory event channels for documentation and characterization of respiratory flow and efforts. If one is suspecting other less common sleep disorders, such as narcolepsy or REM behavioral disorders, full studies would be necessary.

TABLE 129B.3: Recommended definition of respiratory events*

Breathing Events	*Definition*
Apnea	Drop in the peak thermal sensor excursion by ≥90% of baseline, lasting at least 10s, at least 90% of the event's duration meet the amplitude reduction
Hypopnea	Nasal pressure signal excursion drop by ≥30% of baseline lasting at least 10s, with ≥4% desaturation from pre-event baseline, at least 90% of the event's duration meet the amplitude reduction
Respiratory Effort-related Arousals	Sequence of breaths lasting at least 10s characterized by increasing respiratory effort or flattening of the nasal pressure waveform leading to an arousal from sleep when the criteria for an apnea or hypopnea are not met
Types of Respiratory Events	
Obstructive	Continued thoracoabdominal respiratory effort throughout the entire period of reduced/absent airflow
Central	Absent thoracoabdominal respiratory effort throughout the entire period of reduced/absent airflow
Mixed	A respiratory event with both obstructive and central components, beginning with period of absent respiratory effort with resumption of respiratory effort towards the end of the event

*The AASM Manual for Scoring of Sleep and Associated Events 2007

It cannot be over-emphasized that the cost-effectiveness of a diagnostic test does not lie in the test device itself all test results need to be interpreted by someone who knows the test, who can decipher the pitfalls and inaccuracies, and the test results must be correlated with the clinical features for accurate definitive diagnosis and treatment plan in the individual.

MORBIDITIES ASSOCIATED WITH OSA

Neurocognitive and Neurobehavioral Dysfunction

A wide range of neurocognitive deficits are associated with OSA, which may lead to physical or social impairment, compromised quality of life or even depression.[65] Subjects with severe OSA often have impairment in vigilance, concentration, short-term memory and visuomotor skills.[66] Untreated OSA is found to be linked to poorer simulated driving performance[67] and increased risk of road traffic accidents.[68] The implications of OSA and impaired driving performance among occupational drivers cannot be over-emphasized, and they are also exposed to the additional risks of sleepiness caused by shift work, hypnotic and other drug use and alcohol influence.[69-73] Appropriate treatment with nasal Continuous Positive Airway Pressure (CPAP) could reduce the risks of traffic accidents imposed by OSA.[74,75]

These neurocognitive dysfunctions are attributed to the obstructive breathing events causing cerebral arousals and hypoxia during sleep, though the exact contribution of each mechanism is not clearly defined. In recent decade, scientists have uncovered a number of biochemical and molecular changes accounting for the neural injury in the brain as a result of long term intermittent hypoxia using murine models.[76-78]

Systemic Hypertension

Longitudinal and cross-sectional studies have shown a strong association between OSA and systemic hypertension.[79] Hypertension occurs in 30 to 50% of OSA subjects in clinical studies, while 30 to 80% of hypertensive subjects have OSA.[80,81]

The pathophysiology of systemic hypertension in OSA patients is complicated.[81] Compelling evidence has suggested that the activation of sympathetic nervous system and renin-angiotensin axis as a result of arousals and hypoxia led to peripheral vasoconstriction and sustained hypertension. Repetitive cycles of hypoxia also triggered oxidative stress and vascular inflammation, both could lead to increased blood pressure independent of sympathetic activation. A large scale prospective study over 4 years in Wisconsin showed that the odds ratios for developing incident hypertension were 1.4, 2.0 and 2.9 for subjects with AHI 0-4.9, 5-14.9 and ≥15, respectively, compared to those with AHI of zero.[82]

Obstructive sleep apnea is also listed as one of the important predisposing conditions to consider during the workup for resistant hypertension.[83] Systemic review and meta-analyses have included a number of open-label and controlled studies and found a reduction of mean systolic blood pressure of about 2 mm Hg with CPAP therapy and this lowering of mean systolic blood pressure is significant in the terms of alleviation of both cardiovascular, cerebrovascular risk and mortality.[79,84]

Heart Failure

Persistent breathing effort to overcome obstructed upper airway results in significant swing of intra-thoracic pressure, which could lead to increase in left ventricular wall tension. In concert with the repetitive surges of sympathetic activity resulting in increased heart rate and blood pressure, there is an increase in myocardial oxygen demand. Recurrent hypoxia further compromised the oxygen delivery to the myocardium. An epidemiological study in Canada has revealed high prevalence of OSA (26%) and central sleep apnea (21%) in 218 subjects with systolic heart failure.[85] The presence of OSA was reported to be associated with more left ventricular hypertrophy in subjects with nonischemic dilated cardiomyopathy.[86] In a prospective cohort study, following up subjects with systolic heart failure for 2.9±2.2 years, significantly higher mortality occurred in the group with untreated OSA (24%), as compared to the group with mild or no OSA (12%).[85] Randomized trials have convincingly demonstrated the improvement of left ventricular systolic function and lowering of sympathetic activity subsequent to treatment with CPAP in subjects with both heart failure and OSA.[87,88]

Arrhythmia

Obstructive sleep apnea is believed to create an autonomic profile with both profound vagal activity associated with bradyarrhytmias, and sympathetic over-activity leading to tachyarrhythmias and ectopics.[89] In the Sleep Heart Health Study, severe sleep disordered breathing posed two to fourfold higher odds of complex arrhythmias, including Atrial Fibrillation (AF), nonsustained ventricular tachy-cardia and complex ventricular ectopy than those without sleep disordered breathing after adjustment for potential confounders.[90] Patients with untreated OSA had twice the risk of recurrent atrial fibrillation within 1 year of electrical cardioversion to sinus rhythm than those who were treated with CPAP.[91] Treatment of OSA with CPAP for 1 month resulted in 59% reduction in frequency of ventricular premature beats during sleep in heart failure subjects.[92]

Pulmonary Hypertension

Pulmonary hypertension is reported to be present in 20 to 40% of patients with OSA in the absence of other cardio-respiratory disorders.[93] It is often of mild degree (mean pulmonary arterial pressure 30 to 40 mm Hg), while more severe pulmonary hypertension due to severe OSA per se is not common, and has been linked to severe nocturnal desaturations and mortality.[94] In the case of marked pulmonary hypertension, or clinically manifest right heart failure, further considerations should be given to the presence of concomitant diseases, such as obesity hypoventilation syndrome, chronic obstructive pulmonary disease or left heart failure.

Atherosclerotic Diseases

The intermittent hypoxia and sleep fragmentation in OSA are believed to initiate a cascade of pathological events contributing to early atherosclerosis. Oxidative stress, endothelial dysfunction, vascular inflammation and heightened sympathetic activity have been demonstrated in OSA subjects, all of which directly lead to vascular injury. In addition to the prevalent vascular comorbidities (hypertension, diabetes mellitus, obesity), the risk of atherosclerotic vascular disease are much aggravated in OSA subjects.[95] Carotid intima-media thickness, an early sign of atherosclerosis, was shown to be significantly increased in subjects with severe OSA.[96] This is partially reversible with CPAP treatment.[97]

Cross-sectional data from the Sleep Heart Health Study showed greater odds for stroke in the highest AHI quartiles than those with no OSA (OR 1.58). Cohort studies with mean follow up period of 4 to 4.5 years have shown an 2 to 4.5 times increased risk of incident stroke in those with moderate to severe OSA after adjustment for confounders.[98,99] However, whether effective treatment of OSA in stroke survivors improved neurological outcomes remains unanswered, and the application of CPAP in this group of subjects is notoriously limited by poor tolerance and compliance.[99]

Disorders of Glucose Metabolism

The metabolic syndrome, characterized by central obesity, insulin resistance, dyslipidemia and high cardiovascular risks, causes tremendous impacts on the health care system in many developing countries.[3] A number of clinical and epidemiological studies have found an association between OSA and worse insulin resistance, insulin insensitivity and diabetes mellitus.[100]

Recent literature also suggests the occurrence of poorer glycemic control in diabetic subjects with concomitant OSA, as compared to those without OSA.[101] Beneficial effects of CPAP therapy on disorders of glucose metabolism have been demonstrated in some open-label or uncontrolled studies, but the results were inconsistent in a few randomized controlled trials.[100] Well-designed adequately powered randomized trials would resolve such controversy and reveal the benefits of CPAP treatment in terms of clinically interested outcomes. Such pieces of evidence could provide solid ground in better use of public resources in health care planning, particularly in face of resource constraint.

TREATMENT

General Measures

Weight reduction is always advocated for obese or overweight subjects, as improvements in OSA severity and obesity-related complications have been consistently reported.[17] OSA patients should also avoid alcohol, especially in the late evening, and hypnotics (particularly benzodiazepines) as both could reduce muscle tone and aggravate sleep apnea. Maintaining good sleep hygiene could also improve sleep quality. Positional therapy could improve OSA in certain patients whose sleep apnea occurs mainly in the supine position, , but practical ways to achieve consistent lateral posture during sleep are lacking. Treatment of allergic rhinitis potentially alleviates sleep apnea, and would also facilitate the use and acceptance of nasal continuous positive airway pressure.

Continuous Positive Airway Pressure Treatment

Positive airway pressure therapy during sleep applied via the nasal route constitutes the mainstay of treatment for OSA in adults. It acts as a pneumatic splint by delivering a positive intraluminal pressure that maintains the upper airway patency during sleep. It is indicated in patients with severe OSA (AHI ≥30) with or without symptoms, or those with mild-to moderate OSA (AHI 5-30) with symptoms or comorbid conditions (hypertension, heart or cerebrovascular diseases).[102,103] Randomized controlled trials have shown that CPAP not only reduce the AHI, but also improve both subjective and objective sleepiness.[104] Evidence is also available, which reveals its beneficial role in improving quality of life of both patients and bedpartners, reducing risk of motor vehicle accidents, improving blood pressure control and a number of cardiovascular parameters and outcomes.[102,105]

To be effective, the level of CPAP must exceed the critical closing pressure of the upper airway. The treatment pressure is typically determined during an attended in-laboratory CPAP titration with PSG documentation. Alternatively, a split night titration can be undertaken to obtain the diagnosis of OSA in the first half of the night and determine the effective PAP in the later half of the night. Though this can make a better use of the resources, inadequate REM sleep in the early night could potentially lead to underestimation of apnea severity. However, manual titration in the sleep laboratory is resource-demanding and costly. The Autotitrating PAP (APAP) device is increasingly used, in attended or unattended setting, to determine the appropriate treatment pressure, provided that careful patient selection and interpretation of the tracings are pursued. APAP titration, particularly used in home setting, is recently found to be more cost-effective than manual laboratory titration, with similar clinical outcomes.[106] A pressure prediction formula, based on simple anthropometric and sleep variables, has been developed for estimation of therapeutic pressure levels.[107,108] A large multicenter study has shown no difference in CPAP compliance and other outcomes by using prediction formula compared to conventional CPAP titration.[107,109] In-laboratory titrations offers the chance of giving CPAP education to the patients, and this must be adequately provided as outpatient if home titration is being used.

Suboptimal compliance is one of the major limitations in the use of CPAP treatment. Continuous technical advances in the interface and machine algorithm aim to enhance further its user-friendliness. In addition to being a somewhat cumbersome device causing inconvenience, there are a number of side effects that could reduce patient acceptance (Table 129B.4). A comprehensive approach to commencement of PAP treatment, including education, objective adherence monitoring, early intervention for side effects, early clinic follow up, telephone and clinic support is pivotal to optimize compliance. Patients tend to overestimate their own compliance.[110] Most current devices provide objective compliance information on either nightly turn-on time or mask-on time of the PAP. Numerous models of interfaces have also been designed to maximize patient's comfort while avoiding mask-related side effects. In addition to the conventional continuous PAP (CPAP), there are various newer modes of pressure delivery (Bilevel PAP-BPAP, autoadjusting PAP-APAP, flexible PAP) to make patients more comfortable, though evidence showing improved compliance with their use is lacking. Bilevel PAP and autoadjusting PAP are similarly efficacious in reducing daytime sleepiness and controlling apnea as compared to CPAP.[111,112] Heated humidification has been shown to improve compliance, especially in patients with nasal congestion and mucosal dryness.[113,114] These interventions should be implemented as early as possible, as the pattern of use of PAP in the long run is often established in the early course of treatment.[115]

Oral Appliance

Oral appliances (OA) are worn during sleep to increase the dimension of upper airway and reduce its collapsibility. The updated practice parameters recommend their use for mild-to-moderate OSA, or for patients with severe OSA who are unable to tolerate CPAP or refuse CPAP.[116] There are mainly two types of OA: mandibular advancement splints and tongue-retaining devices. Mandibular advancement devices work by anchoring to the dental arches and mechanically protrude the mandible to widen the upper airway. Tongue retaining devices apply suction force to maintain the tongue in a protruded position during sleep, which can be used in edentulous patients. OA is in general less efficacious than

TABLE 129B.4: Common PAP-related side effects and interventions

Side effects	*Interventions*
Mouth dryness	Chin strap, heated humidity, oronasal mask
Airleak with red eyes or noise	Proper mask size and fitting to facial contour, proper mask application
Skin breakdown	Proper mask fitting, avoid over tightening, nasal pillow
Claustrophobia	Nasal pillow, desensitization
Nasal congestion	Nasal steroid, antihistamine, nasal decongestant, heated humidification, oronasal mask
Exhalation difficulty	Lower pressure, Flexible PAP, Bilevel PAP
Pressure intolerance	Ramp, Flexible PAP, Bilevel PAP, APAP
Aerophagia/bloating	Reduce pressure, Bilevel PAP, Flexible PAP

CPAP in controlling OSA (complete response with AHI<5 in 40%, partial response with reduced AHI to less than half in 25%, treatment failure in 35 to 40%), it carries the advantages of being more portable, convenient and thus higher patient acceptance.[117] The reported compliance with OA (77% at 1 year) is higher than that reported with CPAP (about 50% using CPAP for at least 4 hours per night for >70% of nights). Literature is emerging to support the beneficial effect of OA on daytime sleepiness, quality of life, neuropsychological function and blood pressure.[117] Adverse effects of OA include gum and tooth pain, temporomandibular joint discomfort, excessive salivation, while in the long term, dental changes with overbite or overjet. Reassessment PSG with oral appliance is indicated to document the efficacy of OA, as unlike CPAP, its efficacy is not accurately predictable in the individual.

Surgical Options Targeting Upper Airway Obstruction

The aim of OSA surgery is to eliminate anatomical elements contributing to upper airway collapse, or to facilitate functional compensation to reduce airway resistance during sleep, without causing permanent impairment in upper airway function. It is often a second line approach or as an adjunct to other treatment options in the setting of adult OSA.

Tracheostomy has now become obsolete and mainly considered as the last resort for treatment of OSA. Upper airway abnormalities amenable to surgery include those involving the nasal cavity (deviated septum, polyps, hypertrophic turbinates), oropharynx (palatine tonsils, elongated uvula, redundant mucosal folds, low hanging palate) and hypopharynx (lingual tonsils, large tongue base). The role of surgery is more prominent in pediatric OSA than adult OSA, since anatomical obstruction, including enlarged tonsils is a major etiological factor leading to OSA in children and early correction of such anatomical abnormalities is also paramount to prevent abnormal craniofacial development and irreversible damage to pharyngeal dilator reflexes.[118]

Preoperative upper airway assessment is necessary to determine the exact level of obstruction and plan the optimal surgical approach. Preoperative nasopharyngoscopy and cephalometric analysis are performed to identify the site and degree of obstruction. Different surgical procedures address specific airway abnormalities and staged multimodality surgical approach may be required especially in the case of multilevel obstructions. Patients with severe OSA and severe nocturnal desaturation would need to be started on preoperative CPAP and continued postoperatively for weeks until the reassessment PSG.

Uvulopalatopharyngoplasty (UPPP) enlarges the oropharyngeal lumen by removing redundant tissues from the soft palate, tonsillar pillars and uvula. It is currently the most widely performed OSA surgery in adults, and is generally more effective in patients with primarily oropharyngeal obstruction. UPPP is highly effective for reducing snoring, with success rates between 70 to 90%, but the effect of eliminating OSA is much less impressive (significant response with >50% reduction of AHI in 50%, cure rate with AHI<5 in 16% only).[119-121] Furthermore, the therapeutic effect of UPPP is usually not sustained as recurrence occurs in most patients with initial improvement after 5 years. Other surgical options include the reduction of soft tissue by radiofrequency ablation, tonsillectomy, midline glossectomy, maxillomandibular advancement, hyoid myotomy and suspension, genioglossus advancement.[123,124] but both their short or long-term efficacy have not been well documented in adults. Hence, nonselected advocation of surgical treatment for treatment of OSA is not recommended.

Other Treatment Options

Weight loss may be achieved by more aggressive means, such as bariatric surgery and it has been shown to be a highly effective means of treating OSA, in short-term follow up studies. It can be considered in patients with BMI ≥40 kg/m^2 or those with BMI ≥35 kg/m^2 with comorbidities. At one year, a 31% decrease in BMI was accompanied by a 75% reduction in AHI.[125] The problem of recurrent weight gain in the long term poses a concern.

A number of pharmacological agents have been studied previously, but so far no medications are shown to be consistently effective for treatment of OSA. Pharmacologic weight reduction, if effective, will alleviate OSA. Modafinil, a stimulant of central nervous system, was shown in several randomized controlled studies to improve residual sleepiness, vigilance and quality of life in patients with OSA treated with CPAP.[126] However, being a CNS stimulant, its nondiscriminant use is not encouraged, and it is certainly not to be used in itself for the treatment of OSA, as it has no effect on the upper airway obstruction or AHI.[126]

Issues Pertaining to Treatment of OSA in Developing Countries

Despite the fact that CPAP remains the most efficacious treatment of OSA, the high costs in rental, purchase and maintenance could limit its use in resource-limited settings. Notwithstanding, OSA is a chronic disease, with far-reaching adverse effects on health outcomes, personal performance, productivity, quality of life, social consequences. Several economic analyses of CPAP, mainly involving the developed countries, have convincingly demonstrated the cost-effectiveness of CPAP treatment in moderate-severe OSA. It is also highly efficient in reducing motor vehicle crashes and the associated socioeconomic loss.[127-130]

Oral appliances are in general inferior to CPAP in the terms of efficacy, but the higher patient acceptance and probably compliance as well, could potentially magnify its actual benefits in comparison to CPAP. In a recent cost-effectiveness study, CPAP remained the most economically attractive approach compared to OA and lifestyle modification.[131,132] However, such benefits may not be readily extrapolated to the settings in developing countries, since many other diseases and conditions could interfere with health outcomes and productivity to a remarkable degree, so, that the impact from CPAP might become negligible. Cost-effectiveness studies to be carried out in the developing countries would help quantify the exact benefits and assist in health care planning.

To obtain the benefits of CPAP, a set of functional equipment, the accessories and most importantly, the support measures, are required. Adequate education could ensure proper application of the CPAP, improve compliance, and maximize treatment efficacy. Trained personnel in this highly specialized field would be required in order to provide appropriate support to the patients. An efficient and well-trained sleep team and a systematic follow up approach would facilitate the best use of resource in the developing countries.

Respiratory Failure

Karthik Gnanapandithan, Ritesh Agarwal

DEFINITION

Respiratory failure can be defined as a syndrome in which the respiratory system fails to meet one or both of its gas exchange functions, oxygenation and carbon dioxide elimination.[1] In practice, respiratory failure is said to be present if the PaO_2 values are less than 60 mm Hg while breathing room air. It is further classified as type I (or hypoxemic respiratory failure) if the $PaCO_2$ levels are less than 45 mm Hg or type II (or hypercapnic respiratory failure) if the $PaCO_2$ levels are more than or equal to 45 mm Hg.[2] Some authors also classify it further into type III or perioperative respiratory failure and type IV or shock-related respiratory failure. However, there is no specific advantage of these further characterizations.

At sea level, the normal value of PaO_2 in healthy adults is 80–100 mm Hg.[3] This falls progressively with increasing age (approximately 5 mm Hg/decade after 10 years). At 60 years, it is around 75 mm Hg and falls by 1 mm Hg/year, thereafter till the age of 90 years.[4] It is also dependent upon both the concentration of inspired oxygen (FiO_2) and the partial pressure of gas in the atmosphere (P_{atm}). As a rough guide, if PaO_2 is less than five times the fraction of inspired oxygen concentration (FiO_2), patient is probably hypoxemic on room air. Hypoxemia is decrease in the arterial oxygen tension, and is defined as $PaO_2 > 80$ mm Hg while breathing room air. On the other hand, hypoxia defines oxygen depletion at the tissue level. It is important to differentiate between hypoxemia and hypoxia.[5] The classic example is anemia where patients may be hypoxic, but not hypoxemic. Hypoxemia is further classified as mild if PaO_2 <80 mm Hg, moderate if PaO_2 <60 mm Hg and severe if PaO_2 <40 mm Hg.

CLASSIFICATION

The primary functions of the respiratory system are removal of Carbon Dioxide (CO_2) from blood entering the pulmonary circulation, provision of adequate Oxygen (O_2) to blood leaving the pulmonary circulation. If these functions are to be carried out appropriately, there must be adequate fresh air in the alveoli for delivery of O_2 and removal of CO_2 (ventilation), adequate circulation of blood through the pulmonary vessels (perfusion), reasonable movement of gas between alveoli and pulmonary capillaries (diffusion) and appropriate contact between alveolar gas and pulmonary capillary blood (ventilation-perfusion matching).

Respiratory failure may be acute or chronic (Table 130.1). Acute Respiratory Failure (ARF) refers to disorders of recent onset (hours to days). It implies that respiratory failure has developed before physiologic compensation can occur. On the other hand, chronic respiratory failure develops over months to years, allowing compensatory mechanisms to improve oxygen transport and to buffer respiratory acidosis.[6-8] Acute respiratory failure can also be superimposed on chronic respiratory failure, as in acute exacerbations of Chronic Obstructive Pulmonary Disease (COPD). Acute respiratory Failure is characterized by life-threatening derangements in arterial blood gases and acid-base status while the manifestations of chronic respiratory failure are less dramatic and may not be as readily apparent.[9] Acute type-1 respiratory failure is usually seen in diseases of lung parenchyma, cardiovascular system and lower airways. The causes are due to various physiological processes primarily due to ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch but also include other

TABLE 130.1: Causes of respiratory failure

Acute	Chronic

Type 2 Acute exacerbations of chronic obstructive pulmonary disease Tension pneumothorax Guillain-Barrè syndrome Myasthenia gravis Laryngeal edema Inhaled foreign body	*Type 2* Chronic obstructive pulmonary disease Obesity hypoventilation syndrome Motor neuron disease and other neuromuscular disorders

mechanisms such as low inspired concentration of oxygen, impairment of diffusion, intrapulmonary shunting, and low mixed venous oxygen content (Table 130.1).

Mechanisms of Respiratory Failure

Hypoxemic (Type 1) Respiratory Failure

Hypoxemic respiratory failure (also called type 1, nonventilatory or normocapneic respiratory failure) is characterized by a low PaO_2 and a normal or low $PaCO_2$.[10,11] Although there are four pathophysiological mechanisms that can cause hypoxemia, namely low partial pressure of O_2 (FiO_2), diffusion impairment, right-to-left shunt and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, the underlying physiological aberration causing hypoxemia is predominantly $\dot{V}/\dot{Q}$ mismatch. The classic example of acute hypoxemic respiratory failure is the Acute Lung Injury (ALI)/Acute Respiratory Distress Syndrome (ARDS).

Both O_2 and CO_2 diffuse readily down their concentration gradients through the alveolar wall and pulmonary capillary endothelium.[12] Under normal circumstances, equilibration of both the gases is complete within one-third of the transit time of erythrocytes through the pulmonary capillary bed. Thus, even in disease states in which diffusion of gases is impaired, the impairment is unlikely to be severe enough to prevent equilibration of CO_2 and O_2. In patients with interstitial lung diseases, where diffusion is perceived by many as the mechanism of hypoxemia, a diffusion abnormality rarely results in arterial hypoxemia at rest.[13] However, if the transit time in the pulmonary circulation is shortened, as occurs with exercise, and diffusion is impaired, then diffusion limitation may contribute to hypoxemia. Exercise testing can often demonstrate such physiologically significant abnormalities due to impaired diffusion. The ratio of pulmonary ventilation to pulmonary blood flow for the whole lung at rest is about 0.8 to 1 (4–6 liters of minute ventilation divided by 5–6 liters of blood flow every minute). It is this matching of distribution of ventilation and perfusion that is the most important determinant of gas exchange.[14]

The ventilation-perfusion mismatch is the final common pathway to cause hypoxemia in most pulmonary diseases (Fig. 130.1). An area of lung that is well perfused but not ventilated acts as a right to left shunt (physiological shunt) whereas an area that is well ventilated but not perfused acts like a dead space

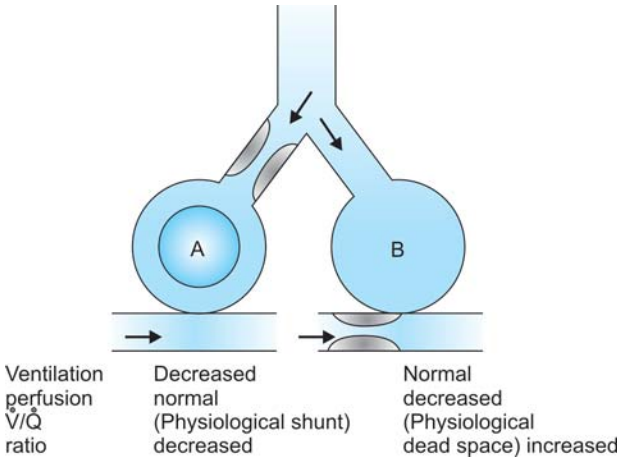

Fig. 130.1: Primary mechanism of hypoxemic respiratory failure—shunt physiology

(physiological dead space). The spectrum of $\dot{V}/\dot{Q}$ ratios in a healthy lung would vary between zero (perfused but not ventilated) to infinity (ventilated but not perfused). The ideal $\dot{V}/\dot{Q}$ ratio of one indicates perfectly matched ventilation and perfusion. Although $\dot{V}/\dot{Q}$ mismatch includes both physiological shunt and physiological dead space but in clinical parlance, the term generally denotes physiological shunt mechanism as physiological dead space, is rarely, if ever the cause of hypoxemia. In an alveolar-capillary unit with a $\dot{V}/\dot{Q}$ ratio of 0 (physiological shunt), the blood leaving the unit has the composition of mixed venous blood entering the pulmonary capillaries, i.e. PO_2 of 40 mm Hg and PCO_2 of 46 mm Hg, whereas in an alveolar-capillary unit with a high $\dot{V}/\dot{Q}$ ratio (physiological dead space) the small amount of blood leaving the unit has partial pressures of O_2 and CO_2 as 150 mm Hg and 0 mm Hg approaching the composition of inspired gas.[13,14]

The efficiency of gas exchange can be evaluated clinically by measuring the PaO_2, $PaCO_2$ and the alveolar-arterial (A-a) DO_2 gradient.[15] Thus, patients with hypoxemia may be divided into those with a normal gradient and those with an increased gradient (Fig. 130.2). The alveolar PO_2 can be calculated from the alveolar air equation:

$$PAO_2 = (P_B - P_{H_2O})\ FiO_2 - (PaCO_2/R)$$

where PAO_2 is the alveolar PO_2, FiO_2 is the fraction of inspired O_2, P_B is barometric pressure (760 mm Hg at sea level), P_{H_2O} is the water vapour pressure (47 mm Hg at sea level) and R is the respiratory exchange ratio (assumed to be 0.8). The alveolar arterial gradient is derived by subtracting PaO_2 from PAO_2. In a healthy individual, the (A-a) DO_2 is normally less than 15 mm Hg at room air; this value increases by 3 mm Hg every decade and can be as high as 30 mm Hg in elderly patients. Hypoxemic respiratory failure most often occurs due to conditions that increase the (A-a) DO_2.[16]

Hypercapnic (Type 2) Respiratory Failure

The normal respiratory rate is about 12–16 times per minute with the tidal volume of each breath being around 500 ml. About 30% of the air inspired with each breath remains in the conducting airways of the lung and does not reach the alveoli. This component of the inspired gas that is not available for gas exchange is called the "anatomic dead space" component. The remaining 70% reaches the alveolar zone and can participate in gas exchange. If the total ventilation each minute is 7 L, then 2 L/min is the dead space ventilation and 5 L/min is the alveolar ventilation. In diseases where some alveoli are ventilated but not perfused, then the component of the anatomical dead space gets increased.[13,14] If total dead space ventilation is increased but total minute ventilation is unchanged, then alveolar ventilation falls. Gas exchange is critically dependent on alveolar ventilation rather than total minute ventilation. The $PaCO_2$ is directly proportional to the amount of CO_2 produced per minute and inversely proportional to alveolar ventilation (V_A), according to the relationship:

$$PaCO_2 = 0.863 \times VCO_2/V_A$$

Fig. 130.2: Importance of calculating alveolar-arterial gradient in patients with acute respiratory failure

where CO_2 is expressed in ml/min, V_A in L/min, and $PaCO_2$ in mm Hg

At fixed CO_2, when alveolar ventilation increases, $PaCO_2$ falls, and when alveolar ventilation decreases, $PaCO_2$ rises. Maintaining a normal level of O_2 in the alveoli (and consequently in arterial blood) also depends on provision of adequate alveolar ventilation to replenish alveolar O_2. Thus, hypercapnic respiratory failure results from any cause that leads to decrease in alveolar ventilation.[6-8,12,15] Multiple mechanisms operate to cause hypercapnia in COPD, the most common cause of type 2 respiratory failure. The mechanisms can be easily remembered by the mnemonic COPD.

- C- central hypoventilation
- O- obstructive physiology with air trapping
- P- peripheral inspiratory muscle weakness due to inflammatory cytokines
- D- diaphragmatic dysfunction.

Clinical Manifestations of Respiratory Failure

A combination of arterial hypoxemia and tissue hypoxia leads to the typical manifestations of hypoxemic failure. Hypoxemia causes hyperventilation due to stimulation of carotid body chemoreceptors with resultant tachypnea. There may be cyanosis, the degree of which depends on the concentration of the hemoglobin and the patient's perfusion. Hypoxia stimulates anaerobic metabolism with the generation of lactic acid that further stimulates ventilation. Mild hypoxia may also lead to impaired mental performance. With progression of hypoxia alteration in the sensorium, somnolence, coma and seizures can occur, leading to permanent brain damage. Hypoxemia causes stimulation of the sympathetic nervous system, and resultant tachycardia, diaphoresis and systemic vasoconstriction. Severe hypoxia can lead to bradycardia, vasodilation, hypotension, myocardial ischemia, infarction, arrhythmias and cardiac failure. Symptoms and signs also reflect not just acute hypoxemia, but also the underlying cause of respiratory failure. Patients with acute hypercapnic respiratory failure largely present with central nervous system disturbances. Hypercapnia causes central nervous system depression leading to lethargy, somnolence, coma, asterixis, restlessness, tremors, slurred speech, headache and papilledema. Symptoms of hypercapnia may overlap those of hypoxemia.

Diagnosis

Arterial Blood Gas Analysis

Respiratory failure may be associated with a variety of clinical manifestations. As these are nonspecific and respiratory failure may be present without dramatic signs or symptoms, this emphasizes the importance of measuring arterial blood gases in all patients in whom respiratory failure is suspected. The arterial blood gas analysis measures pH, PaO_2, $PaCO_2$ and HCO_3. The partial pressure is the driving pressure for the gas in blood and not a measure of the quantity of gas in the blood. Thus, the actual O_2 content in the blood depends on the solubility of O_2 in plasma and the quantity of hemoglobin. The PaO_2 determines what percentage of hemoglobin is saturated with O_2, based on the position on the oxyhemoglobin dissociation curve. Oxygen content in blood can be determined by adding the amount of O_2 dissolved in plasma to the amount bound to hemoglobin, according to the equation:

$$O_2 \text{ content} = 1.34 \times [\text{hemoglobin}] \times O_2 \text{ saturation} + 0.0031 \times PaO_2$$

In arterial blood, the amount of O_2 transported dissolved in plasma (approximately 0.3 ml O_2 per deciliter of blood) is trivial compared to the amount bound to hemoglobin (approximately 20 ml O_2 per deciliter of blood). In arterial blood gas analysis, PaO_2 is the measurement used to assess the effect of respiratory disease on the oxygenation status. The PaO_2 gives an assessment of the hypoxemia whereas the oxygen content denotes the level of hypoxia.[16]

Pulse Oximetry

Pulse oximetry is a noninvasive assessment of the oxygenation status, as measurement of PaO_2 requires arterial puncture. The pulse oximeter calculates oxygen saturation (rather than PaO_2) based on measurements of absorption of two wavelengths of light by hemoglobin in pulsatile, cutaneous arterial blood. Due to differential absorption of the two wavelengths of light by oxygenated and nonoxygenated hemoglobin, the percentage of hemoglobin that is saturated with oxygen, i.e. the SaO_2 can be calculated and displayed instantaneously. As oxyhemoglobin dissociation curve becomes relatively flat above PaO_2 of 60 mm Hg (corresponding to SaO_2 of 90%), the oximeter is relatively insensitive to changes in PaO_2 above this level. In conditions where cutaneous perfusion is decreased such as hypotension, the signal from the oximeter may be less reliable or even unobtainable. Other forms of hemoglobin, such as carboxyhemoglobin and methemoglobin, are not distinguishable from oxyhemoglobin when only two wavelengths of light are used. The SaO_2 values are not reliable in the presence of significant amounts of either of these forms of hemoglobin. Finally, the pulse oximeter does not indicate anything about CO_2 elimination.[16]

Chest Radiograph

Chest radiography is essential because it frequently reveals the cause of respiratory failure. However, distinguishing between cardiogenic and noncardiogenic pulmonary edema often is difficult, and may require clinical judgement and echocardiography.

Pulmonary Function Tests (PFTs)

Generally PFTs should not be performed in patients with ARF. However, PFTs are valuable in the evaluation of chronic respiratory failure.

A decrease in Forced Expiratory Volume in one second/Force Vital Capacity ratio indicates airflow obstruction, whereas a reduction in both the FEV_1 and FVC and maintenance of the FEV_1/FVC ratio suggest restrictive lung disease. Respiratory failure is uncommon in obstructive diseases when the FEV_1 is greater than 1 L and in restrictive diseases when the FVC is more than 1 L.

Treatment

The principles of managing respiratory failure are outlined below:

- As most patients are critically ill, management should take place in a high dependency unit/intensive care unit (ICU) setting.
- Alleviation of hypoxia is the immediate aim of treatment.
- Treatment of basic underlying condition such as pneumonia, pulmonary edema, etc.
- Support with mechanical ventilation either noninvasive or invasive. This is to "buy" time for specific therapies such as antibiotics to act.

Oxygen Therapy

Hypoxemia is the major immediate threat to organ function. Therefore, the first objective is to reverse and/or prevent tissue hypoxia.[13] Oxygen therapy is started immediately on admission after an arterial blood sample is obtained for assessment of blood gas tensions. The goal of supplemental oxygen is to maintain a PaO_2 of 55–60 mm Hg corresponding to SpO_2 of 89–92%. A common mistake committed by physicians, nursing staff and occasionally the patient's attendants is to increase the flow of oxygen to improve oxygen saturation. However, one should not forget that oxygen is a "drug" and should be carefully administered since excess oxygen has got its own problems. In a patient with COPD who has chronic type II respiratory failure and hypercapnia, the ventilatory stimulus for hypercapnia is lost and patients' ventilatory drive is maintained by hypoxemia. Administration of excess amounts of oxygen can blunt this ventilatory drive with resultant hypercapnia and acute respiratory acidosis superimposed on type II respiratory failure that could be potentially life-threatening. Excess oxygen therapy has been shown to prolong hospital stay probably because it can lead to generation of harmful reactive oxygen species, which can exacerbate tissue injury. Excess oxygen can also lead to hypercapnia by ventilation perfusion disturbances, Haldane effect and by causing numerous areas of microatelectasis. Another reason why PaO_2 is not increased more than 60 mm Hg is because it corresponds to oxygen saturation (SaO_2) of around 90%; from the oxygen content equation we can conclude that there is no benefit of increasing PaO_2 above 60 mm Hg except in situations of hyperbaric oxygen delivery. In arterial blood, the amount of O_2 transported dissolved in plasma (approximately 0.3 ml O_2 per deciliter of blood) is trivial compared to the amount bound to hemoglobin (approximately 20 ml O_2 per deciliter of blood). Due to the sigmoid shape of the oxyhemoglobin dissociation curve, it is important to differentiate between the partial pressure and the content of oxygen in the blood. The partial pressure is only the driving pressure for the gas in blood and not a measure of the quantity of gas in the blood. Thus, the actual O_2 content in the blood depends on the solubility of O_2 in plasma and the quantity of hemoglobin. The PaO_2 determines what percentage of hemoglobin is saturated with O_2, based on the position on the oxyhemoglobin dissociation curve. Hemoglobin is almost fully (>90%) saturated at a PO_2 of 60 mm Hg and little additional O_2 is carried by hemoglobin even with a substantial elevation of PO_2 above 60 mm Hg. On the other hand, significant O_2 desaturation of hemoglobin occurs once PO_2 falls below 60 mm Hg and onto the steep descending limb of the curve.

Another important consideration in acutely ill patients is the type of oxygen delivery device which is used. Low-flow oxygen delivery systems provide oxygen at flow rates that are lower than patient's inspiratory demands; thus when the total ventilation exceeds the capacity of the oxygen reservoir, room air is entrained.[17-19] The final concentration of oxygen delivered depends on the ventilatory demands of the patient, the size of the oxygen reservoir and the rate at which the reservoir is filled. At a constant flow, the larger the tidal volume, the lower the FiO_{2-} and vice versa.[13] In contrast, the high-flow systems provide a constant FiO_2 by delivering the gas at flow rates that exceed the patient's peak inspiratory flow and by using devices that entrain fixed proportion of room air. In acute situations, it is always better to use high-flow devices as one can, to a reasonable extent, guarantee the oxygen delivered. On the other hand, with the use of a low flow device, oxygen delivery would not be dependent on the patient's minute ventilation. Once the patient has been stabilized, one can shift to nasal prongs, as it proves more comfortable for the patient.

The appropriate FiO_2 is selected with the help of alveolar gas equation.[13] We also know that the ratio of PaO_2 to P_AO_2 is independent of FiO_2. For example, a patient of COPD has PaO_2 of 35 mm Hg and $PaCO_2$ of 58 mm Hg on room air; the FiO_2 requirement to bring PaO_2 of 60 mm Hg is calculated as follows:

$P_AO_2 = [FiO_2 (P_{atm} \text{ minus } P_{H_2O})] - (PaCO_2/R)$

$= [0.21 (760\text{-}47)] - (58/0.8) = 77.3$

$PaO_2/P_AO_2 = 35/77 = 0.45$

To get the desired PaO_2 of 60 mm Hg, the P_AO_2 must increase for the same PaO_2/P_AO_2 ratio, i.e.

$35/77 = 60/\ P_AO_2\ (x) = 0.45$

$P_AO_2\ (x) = 77 \times 60/35$

$P_AO_2 = 133.3$

The desired FiO_2 (for PaO_2 of 60 mm Hg) can be determined again from the alveolar gas equation as above, i.e.

$133 = FiO_2 \times 713\text{-}\ (58/0.8)$

$FiO_2 = 28.8$

Noninvasive Ventilation (NIV)

Noninvasive ventilation refers to the provision of inspiratory pressure support plus Continuous Positive Airway Pressure (CPAP) via a nasal or facemask, i.e. without an endotracheal airway.[20-25] It has been used for diverse forms of respiratory failure and has revolutionized the management of respiratory failure.[26-32] Although CPAP does not actively assist inspiration and is not traditionally a ventilatory mode, it is considered a form of NIV when used as a therapy for respiratory failure. The key to the successful application of NIV is identification of the appropriate patient for its use. Once patients who require immediate intubation are eliminated, a careful assessment of the patient's condition determines whether the patient requires NIV.[21] This requires clinical evaluation and may also involve a NIV trial. NIV is an effective tool in improving the clinical outcome of patients with different etiologies of ARF especially acute exacerbations of COPD,[33] cardiogenic pulmonary edema,[20,21] weaning patients with chronic respiratory failure especially COPD[34] and management of ARF in immunocompromised patients.[35,36] It not only avoids the need for endotracheal intubation but also reduces other complications such as occurrence of nosocomial infections, duration of ICU stay and the overall cost of hospitalization.[37]

Important determinants of NIV success are properly fit and comfortable interface and ventilator settings.[21,32] Masks are firmly secured with elastic straps to the face in order to avoid air leaks and consequent malfunction. The nasal mask is usually well tolerated because it causes less claustrophobia and discomfort.[38] It allows eating, drinking and expectorating. Conversely, a facial mask is preferable in severe respiratory failure, because dyspneic patients breathe through the mouth in order to bypass resistance of the nasal passages, and mouth opening during nasal mask ventilation results in air leakage and decreased effectiveness.[39] Hence, full facemasks are utilized for ARF whereas nasal masks are preferred for use in the chronic setting. The optimal ventilator settings are determined by the ability to reduce the work of breathing (assessed clinically by reduction in respiratory rate to <30–35 breaths per minute) by providing an adequate level of pressure support (usually >8–10 cm H_2O) against the discomfort imposed by high pressures (Table 130.2).

The application of NIV should be performed in an area where there is constant availability of adequate staff that is trained in use of NIV.[40] To assure the success of NIV, close monitoring is necessary, especially during the initial period. The patients need to be monitored with regular clinical observation, continuous pulse oximetry and on-demand arterial blood gas measurements. Favorable subjective responses such as tolerance of the mask and NIV pressures and reduction of respiratory distress further help achieve good results. Although the optimal duration of the initial NIV trial remains uncertain, a response within 1–4 hours of initiation is a reasonable expectation.[41] Finally, patients who are failing

TABLE 130.2: Protocol for application of noninvasive ventilation in acute respiratory failure

- Full facemask better tolerated in the acute setting
- Start with an inspiratory pressure support of 6–8 cm H_2O and CPAP of 3–4 cm H_2O
- Adjustments
  - Increase inspiratory pressure and CPAP by 2 and 1 cm H_2O, respectively
  - Titrate to tidal volume (>5 ml/kg), respiratory rate (<35 breaths/minute) and blood gases
  - Maximum inspiratory pressure and CPAP generally used is 15–16 cm H_2O and 7–8 cm H_2O, respectively
- Air leaks should be minimized
- CPAP is rarely used in acute respiratory failure.

NIV trial should be promptly intubated and mechanically ventilated as delays in endotracheal intubation in patients being managed with NIV have been shown to be associated with decreased survival.[42]

We have significant experience with the use of NIV. In a study involving 63 patients, NIV failures were higher in ARF associated with other causes (15/39, 38.4%) compared to ARF associated with COPD (3/24, 12.5%). Only the etiology of ARF (ARF due to other causes) was associated with NIV failure on a multivariate analysis.[23] In another study involving 40 patients with hypoxemic ARF, NIV failures were higher in ARDS group (12/21, 57.1%) than hypoxemic ARF due to other causes (7/12, 36.8%). The only factor associated with NIV failure was the baseline PaO_2-FiO_2 ratio on a univariate analysis.[24] In a recently conducted randomized controlled trial, we randomized patients with acute asthma to the standard medical therapy (SMT) arm (n=28) or NIV plus SMT (n=25). The improvement in respiratory rate, FEV_1 and PaO_2-FiO_2 were seen equally in both groups. However, increment in FEV_1 by 50% at 4 hours was greater in the NIV arm. Not only the mean dose of broncho-dilators required was lesser in the NIV group, but the ICU and hospital length of stay was significantly shorter in NIV group. There were four instances of SMT failure and all these patients improved with the application of NIV. Two patients failed NIV and required endotracheal intubation.[43]

Endotracheal Intubation and Invasive Ventilation

Patients who are in severe respiratory distress and those who fail treatment with oxygen and NIV generally require endotracheal intubation and invasive ventilation. Another indication for intubation is airway protection in patients with altered mental status. The aim of invasive ventilation is to correct hypoxemia and maintain alveolar ventilation appropriate to patient's metabolic requirements. It has been recognized since 1970 that mechanical ventilation, if not applied properly, could cause harm.[44] However, only recently this concept has been applied in day-to-day practice. A new era of ventilatory management began in 1990 when it was showed that minimizing pulmonary overdistension and allowing permissive hypercapnia decreased mortality in patients with ARDS.[45] The clinical importance of ventilator associated lung injury was aptly highlighted by the ARDS Network study.[46] Although patients without ALI are still ventilated with large tidal volumes, recent studies have shown that use of higher tidal volumes can cause ventilator associated lung injury even in patients with normal lungs.[47-55] Recognition of this fact has led to paradigm shift in the ventilatory management with use of lower tidal volumes even in patients with normal lungs. The current ventilatory strategy aims at minimizing complications of mechanical ventilation. The principles are to prevent initiation of additional alveolar injury and facilitate healing of the underlying condition. The ventilation is thus pressure targeted employing lower tidal volumes. The aim is to have adequate blood gases and normalization of physiological parameters is not considered important (Table 130.3).

An important consideration is the choice of ventilator that should be used for mechanically ventilating these patients. No ventilator is clearly better than any other. The machine is selected based on the spectrum of patients, the financial resources of the ICU and the available expertise in handling the equipment. Clearly, the people operating the ventilator are more important

TABLE 130.3: Parameters and goals for invasive mechanical ventilation in different categories of respiratory failure

	Restricted lung	Obstructed lung	Normal lung
Prototype	ARDS	Acute asthma	Neuromuscular respiratory failure
Mode	V-ACMV	V-ACMV	V-ACMV
Initial tidal volumes	4–6 ml/kg	4–6 ml/kg	6–8 ml/kg
Respiratory rate	18–35/minute	8–12/minute	14–18/minute
PEEP	Based on FiO_2; 0.XX (FiO_2) x 20	5–8 cm H_2O	Up to 5 cm H_2O
I:E	1:1–1:2	1:3–1:6	1:2–1:3
Flow waveform	Descending ramp	Square waveform	-
	Goals		
Plateau pressure	≤ 30 cm H_2O	≤ 30 cm H_2O	-
PaO_2	~ 55–60 mm Hg	~ 55–60 mm Hg	~ 60–80 mm Hg
pH	7.2–7.4	7.2–7.4	-

than the machine. Other important issue is the mode to be used for mechanical ventilation. Again no mode is clearly superior. The choice of a particular mode is often guided by institutional policy or personal preference. Another controversial area is the choice of a volume controlled or pressure controlled strategy. There is no strong evidence base for the pressure controlled ventilation although logically it is likely to be equivalent to the volume controlled mode because it is the settings rather than the mode that is the important issue. It is best to initiate ventilation with a volume assist controlled mode ventilation and once the patient improves, shift the patient to pressure support ventilation. As a protocol, we rarely if ever use synchronized intermittent mandatory ventilation for either initial ventilation or later for weaning. Newer modes of ventilation are increasingly being promoted to decrease the hazards of conventional ventilation and improve patient-ventilator interactions. However, none of the newer modes of ventilation has been shown superior to conventional modes. Also, the indications, efficacy and safety are still clinically uncertain and are not being widely utilized.

CONCLUSION

In conclusion, the management of respiratory failure hinges on two basic principles, i.e. oxygen therapy for alleviation of hypoxemia and aggressive treatment of basic disease. Oxygen should be administered through high-flow (Venturi mask) system. NIV should be judiciously used in ARF as inappropriate use of NIV may lead to delayed intubation in some patients. Eventually, mechanical ventilation is required in patients who fail NIV or develop respiratory arrest.

Acute Respiratory Distress Syndrome

Jean I Keddissi, D Robert McCaffree

The Acute Respiratory Distress Syndrome (ARDS) is a serious and frequently encountered entity in modern intensive care units. Since its initial description in 1967 by Ashbaugh et al,[1] our understanding of its epidemiology, pathophysiology and clinical course have greatly improved. This has recently resulted in management changes, which are affecting outcome, and are likely to result in newer therapeutic modalities.

In this chapter, we will review the current knowledge of ARDS. We will also review in details all the available therapies, with focus on the large trials that have enhanced our understanding of this syndrome.

Definition

For decades, attempts to define ARDS lacked specific criteria,[2,3] causing uncertainty in terms of its true incidence, natural history and appropriate management. Initially called the adult respiratory distress syndrome, the term acute respiratory distress syndrome is now used since it does occur in children.

In 1994, an American/European Consensus Conference[4] proposed the following clinical criteria to define the syndrome: Presence of acute widespread, bilateral radiographic infiltrates on the chest X-ray, hypoxemia ($PaO_2/FiO_2 < 200$), without any evidence of left atrial hypertension. Acute Lung Injury (ALI), a less severe and often earlier form of ARDS, is considered present if PaO_2/FiO_2 is <300. The definition is simple and takes into consideration the severity of the lung injury, expressed as the degree of hypoxemia (ARDS versus ALI). However, it does not take into consideration the underlying cause, nor does it consider any accompanying extrapulmonary manifestation. In addition, it does not incorporate any physiological measurement of lung mechanics. Nevertheless, the 1994 definition has gained widespread acceptance and is now being used in daily practice as well as in clinical trials.

Epidemiology

Estimates of the true incidence of ARDS and ALI varied widely, in part due to the lack of a uniform definition. Estimates ranged from 1.5 to 75 cases per 1,00,000 people.[5] The first estimates based on the 1994 definition used an 8-week prospective cohort study in Scandinavia and reported an incidence of 17.9 cases of ALI and 13.5 cases of ARDS per 1,00,000.[6] More recently, a prospective, population-based, cohort study in 21 hospitals in and around King County, Washington, from April 1999 through July 2000, ARDS was estimated to occur in 64 cases/1,00,000 person-years, while ALI occurred in 86 cases/1,00,000 person-years.[7]

Etiology

Sepsis remains the most common cause of ARDS and carries the worst prognosis,[8] with 40% of sepsis cases developing ALI or ARDS.[9,10] Other frequently encountered etiologies include pneumonia (bacteria, virus, fungal), aspiration, shock and trauma (Table 131.1). The presence of multiple predisposing factors increases the risk significantly.[10] Additionally, observational data suggest that inappropriate ventilatory settings in mechanically ventilated patients may contribute to the development of ARDS (i.e. iatrogenic ARDS).[11]

TABLE 131.1: Clinical entities associated with ARDS/ALI

- Acute pancreatitis
- Acute upper airway obstruction
- Aspiration (gastric acid, near drowning)
- Drugs (amiodarone, tocolytics, salicylates, opiates, etc.)
- Iatrogenic ARDS
- Inhalation injury
- Neurogenic pulmonary edema
- Nonthrombotic embolic events (amniotic, tumor, etc.)
- Pneumonia
- Pulmonary embolism
- Reperfusion injury (postlung transplant, lung re-expansion)
- Sepsis (most common)
- Shock
- Transfusion-related acute lung injury (TRALI)
- Trauma.

Clinical Picture

Clinically, the picture is characterized by the rapid onset of hypoxemic respiratory failure, in a patient with a predisposing underlying condition. The hypoxemia is typically refractory to oxygen replacement, frequently requiring the institution of invasive mechanical ventilation. Radiographically, bilateral patchy or asymmetric infiltrates are present, frequently indistinguishable from those seen in cardiogenic pulmonary edema.[12] Computed Tomography (CT) typically reveals areas of consolidation, alveolar filling with atelectasis, predominantly in the dependent zones (Fig. 131.1).[13] In later stages, the CT may reveal diffuse interstitial opacities, with bullae formation. Pulmonary compliance is decreased[14] and evidence of pulmonary hypertension and right ventricular failure may be seen.[5] Pneumothorax may develop in 10 to 13% of the cases, but is not clearly related to the airway pressures, nor is it associated with a significantly increased mortality rate.[15]

Pathophysiology

ARDS is a progressive syndrome, characterized by distinct histopathological stages (Fig. 131.2). Initially, an acute, exudative stage is characterized by the presence of alveolar edema in the absence of an elevated hydrostatic pressure. This edema is secondary to capillary injury, with increased alveolar-capillary membrane permeability, a feature considered to be the hallmark of ARDS. The normal alveolar epithelium is also affected, with the flat type I cell (typically making up 90% of the surface area) easily injured. Cuboidal type II

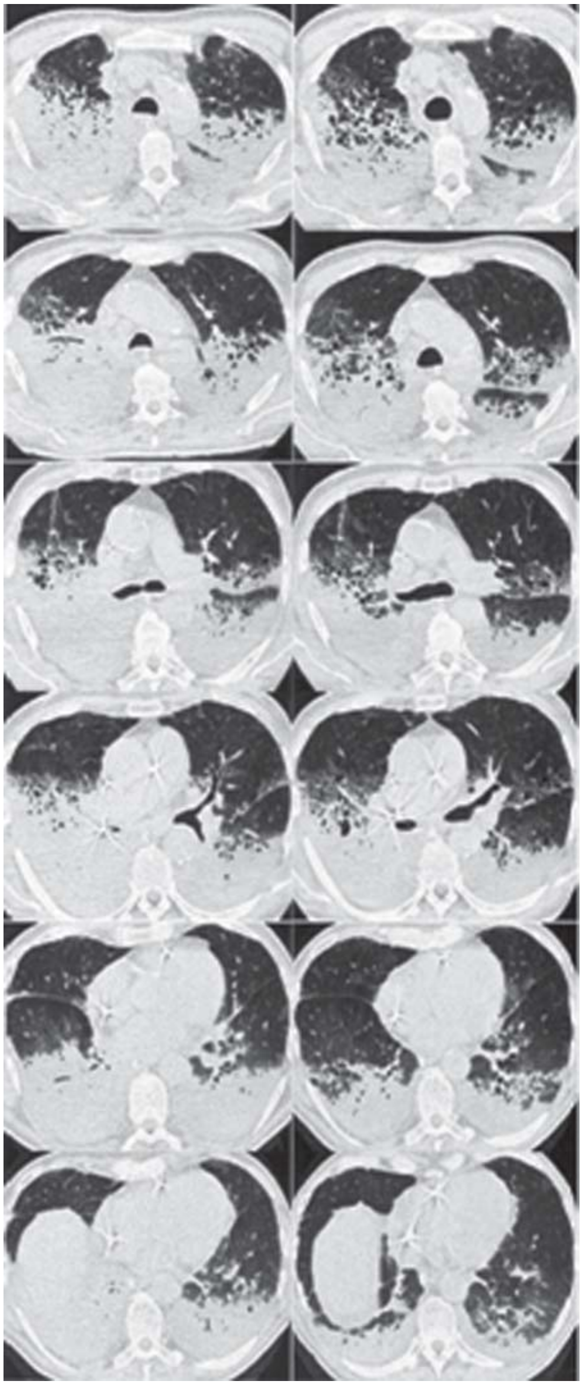

Fig. 131.1: Computed tomographic scans obtained in a 61-year-old patient with "patchy" acute respiratory distress syndrome caused by aspiration pneumonia in the postoperative period of a hip replacement. A selection of contiguous 1 cm thick computed tomographic sections obtained with zero end-expiratory pressure (left images) and positive end-expiratory pressure (PEEP) of 15 cm H_2O (right images) is presented (Adapted with permission from Rouby et al)[13]

Fig. 131.2: The normal alveolus (left-hand side) and the injured alveolus in the acute phase of ALI/ARDS syndrome (right-hand side). In the acute phase of the syndrome (right-hand side), there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are shown adhering to the injured capillary endothelium and marginating through the interstitium into the air space, which is filled with protein-rich edema fluid. In the air space, an alveolar macrophage is secreting cytokines (IL-1, 6, 8, and 10, and TNF-α), which act locally to stimulate chemotaxis and activate neutrophils. Macrophages also secrete other cytokines, including IL-1, IL-6 and IL-10. IL-1 can also stimulate the production of extracellular matrix by fibroblasts. Neutrophils can release oxidants, proteases, leukotrienes and other proinflammatory molecules such as platelet-activating factor (PAF). A number of anti-inflammatory mediators are also present in the alveolar milieu including IL-1 receptor antagonist, soluble TNF receptor, autoantibodies against IL-8 and cytokines such as IL-10 and IL-11 (not shown). The influx of protein rich edema fluid into the alveolus has led to the inactivation of surfactant. MIF denotes macrophage inhibitory factor (Adapted with permission from Wade et al)[5]

cells are typically more resistant and would eventually differentiate into type I after injury, restoring the normal alveolar architecture.[5]

As a result, massive amount of edema fluid and plasma proteins leak into the alveolar space, with subsequent formation of hyaline membranes. These membranes appear in the first 24–48 hours, reach a maximum around day 4 and start to decrease after 6–7 days.[16,17] In addition, fluid removal from the alveolar space is significantly impaired in the majority of patients and maximal alveolar fluid clearance, when present, may be associated with better clinical outcomes.[18]

Activated inflammatory cells, primarily macrophages and neutrophils, accumulate in the interstitium. Whether these cells are the cause or the results of the lung injury is not entirely known. Proinflammatory cytokines are released into the lungs including Interleukin (IL)-1β, IL-8 and tumor necrosis factor (TNF)-α.[19,20] These cytokines play a major role in the lung response to infection or injury, but have a potential role in the cellular response, microvascular injury and the extrapulmonary organ failures seen in ARDS.[20] In addition, neutrophil matrix metalloproteinase (MMP)-9 level is significantly increased.[19] Studies have also shown the presence of anti-inflammatory cytokines such as IL-10 and IL-11, and inhibitors of proinflammatory cytokines including IL-1 receptor antagonist and soluble TNF receptor.[21,22]

Surfactant activity and composition is altered, resulting in elevated surface tension, leading to alveolar collapse.[23] This contributes to the development of decreased lung compliance seen in ARDS/ALI.[24] Furthermore, the presence of excess protein in the alveolar space leads to the disintegration of the large phospholipids macroaggregates into smaller aggregates, which are less active and dysfunctional[25,26] (Fig. 131.3). In addition to the decreased lung compliance, this results in impaired gas exchange and increased pulmonary arterial pressures.[27,28]

Although the above injury may resolve completely after the acute phase, some patients progress and develop evidence of pulmonary fibrosis, with persistent hypoxemia. The alveolar space becomes filled with mesenchymal cells, their products, in addition to new blood vessels.[29] When present, the fibrosis starts around day 3 and becomes dominant at day 7, leading experts to consider day 7 as the cutoff between the early stage (exudative phase) and late stage (proliferative phase) of ARDS. Finally, it appears that the presence of pulmonary fibrosis, diagnosed on the basis of fiberscopic transbronchial lung biopsy, closely correlates with mortality in established ARDS.[30]

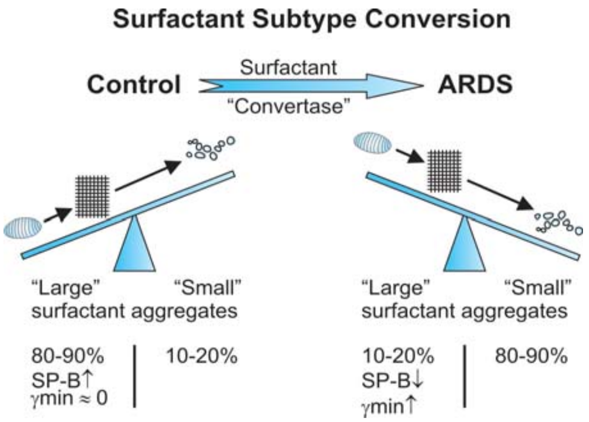

Fig. 131.3: Surfactant containing protein B (SP-B) or C (SP-C) is generally more resistant to plasma protein inhibition (surfactant convertase). These hydrophobic proteins help to maintain the integrity of the large aggregate forms of surfactant that would otherwise be converted rapidly into less active small aggregates in the presence of excess protein (Adapted with permission from Dernaika et al)[20]

Management

General Measures

Careful search of the underlying etiology is crucial in the management of patients with ARDS. Treatable infections should be addressed and the need for surgical drainage evaluated. The patients should be monitored for the development of nosocomial infections. Adequate nutrition should be provided, with the enteral route always preferred when feasible. In addition, patients should be placed on prophylaxis against gastrointestinal bleeding and thromboembolic events.

Invasive Mechanical Ventilation

Endotracheal intubation and mechanical ventilation are almost always needed in patients with ARDS. Mechanical ventilation aims to correct the severe hypoxemia encountered in this setting. Historically, normalizing the partial pressure of carbon dioxide was also considered a primary goal. Although life saving, it became gradually evident that mechanical ventilation can have major negative consequences in terms of exacerbating lung injury through a process termed as Ventilator-induced Lung Injury (VILI). Until recently, few prospective randomized trials have addressed the optimal way of ventilation patients with this syndrome.

Tidal Volume

Achieving normal blood gas parameters was historically done at the expense of high tidal volume. Tidal volumes in excess of 10 ml per kilogram of ideal body weight were used.[31] High tidal volume and high airway pressures were thought to be beneficial in opening collapsed alveoli (i.e. recruitment). However, if one considers the fact that collapsed alveoli have low compliance and do not adequately participate in tidal ventilation, the potential for injury with the use of high pressure/volume becomes evident. In fact, the volume of aerated lung in patients with ARDS is significantly reduced. Therefore, these aerated units are at an increased risk of hyperinflation, not only in the presence of high tidal volume and high transpulmonary pressure, but even at modest pressures.[32] Hyperinflation and overdistention leads to the development of VILI. Consequences include disruption of the alveolar epithelium and capillary endothelium.[33] In addition, evidence clearly show that overdistention will result in an inflammatory process involving cytokines and mediators release,[32,34] a process that appear to be systematic in nature, possibly contributing to the development of multisystem organ failure.[35]

Based on theoretical and animal data, the American College of Chest Physicians recommended in 1993 that patients with ARDS be ventilated with a plateau pressure that is less than 35 cm of H_2O.[36] This was followed by the first clinical trial to support the benefit of a low tidal volume strategy. Amato et al randomly assigned 53 patients with early ARDS to conventional ventilation (tidal volume of 12 ml/kg of body weight, $PaCO_2$ levels of 35–38 mm Hg and lowest PEEP for acceptable oxygenation) versus protective mechanical ventilation (tidal volume <6 ml/kg, permissive hypercapnia, PEEP above the lower inflection point on the static pressure-volume curve, driving pressures <20 cm H_2O above PEEP and preferential use of pressure limited ventilatory modes).[37] As compared to conventional ventilation, the protective strategy was associated with decreased 28-day mortality (38% versus 71%, p<0.001), a higher rate of weaning from mechanical ventilation and a lower rate of barotraumas. However, the difference in the rate of survival to hospital discharge did not reach statistical significance (45% versus 71%, p=0.37).

Based on this preliminary data, the Acute Respiratory Distress Syndrome Network (ARDSNet) conducted a larger study (861 patients),[38] comparing traditional ventilation treatment, which involved an initial tidal volume of 12 ml/kg of predicted body weight with a plateau pressure of 50 cm of H_2O or less, with ventilation with a lower tidal volume, involving an initial tidal volume of 6 ml/kg of predicted body weight and a plateau pressure of 30 cm of water or less. The study used a predetermined combination of FiO_2 and PEEP (Table 131.2), with a PaO_2 goal of 55–80 mm Hg, or an oxyhemoglobin saturation of 88 to 95%. Mortality was lower in the group treated with lower tidal volumes than in the group treated with traditional tidal volumes (31.0% versus 39.8%, P=0.007). In addition, the number of days without ventilator use during the first 28 days after randomization was greater in the low tidal volume group (12±11 versus 10±11; P=0.007). Finally, the study showed a lower plasma interleukin-6 concentration in the low tidal volume group, indicating that the low tidal volume strategy has beneficial systemic anti-inflammatory consequences.

TABLE 131.2: Combination of FiO_2/PEEP in the ARDSnet trial.[38] The lowest combination that maintained a PaO_2 of 55–80 mm Hg or an oxyhemoglobin saturation of 88 to 95%, was used

FiO_2	Positive end-expiratory pressure
0.3	5
0.4	5–8
0.5	8–10
0.6	10
0.7	10–14
0.8	14
0.9	14–18
1.0	18–24

At this point, one can ascertain that a tidal volume of 6 ml/kg is better than 12 ml/kg in ARDS. However, it is important to use the ideal body weight, and not the actual weight, to calculate the tidal volume. The ideal body weight (IBW) can be calculated as follows: For men, IBW = 50.0 + 0.91 (height in cm=152.4); and for women, IBW = 45.5 + 0.91 (height in cm=152.4).[33] One also has to remember that the use of low tidal volume can result in CO_2 retention, i.e. permissive hypercapnia with respiratory acidosis. This could be treated with a higher respiratory rate and with the administration of sodium bicarbonate. The latter remains controversial, and likely unnecessary except in the presence of severe acidosis. However, the exact pH at which the use of bicarbonate is necessary (if at all) remains controversial,[33] with some experimental data suggesting that permissive hypercapnia is not only safe, but potentially beneficial.[39] Nevertheless, it should be used carefully in patients with heart disease and is relatively contraindicated in patients with elevated intracranial pressure.

In addition, several questions remain unanswered. Is an intermediate tidal volume an acceptable alternative? And would an even lower tidal volume (less than 6 ml/kg) provide any additional benefit, especially in the presence of high plateau pressure? And can a higher tidal volume in the presence of low plateau pressure (i.e. high respiratory system compliance) be used safely? Finally, whether low tidal volume would be beneficial in nonARDS respiratory failure is unknown. These questions remain open to debate and will require large prospective randomized trails to answer.

Positive End-expiratory Pressure (PEEP)

An arterial oxyhemoglobin saturation of about 90% is typically targeted in patients with ARDS. This may be difficult to achieve, even in the presence of high FiO_2. This constitutes the- main indication for PEEP in ARDS. It is used primarily as a means of supporting oxygenation, PEEP increases the functional residual capacity and prevents small airways and alveoli from collapsing, leading to improvement in the ventilation-perfusion ($\dot{V}/\dot{Q}$) matching.[40-42] It also prevents the repetitive opening and closing of alveoli, referred to as atelectrauma. However, the prophylactic use of PEEP at 8 cm H_2O in patients at risk for ARDS was not successful.[43]

Clinicians have to be aware of the potential for side effect associated with PEEP, primarily circulatory depression and barotrauma. Consequently, the concept of best PEEP in ARDS remains elusive, with some advocating the use of the pressure-volume curve as a means to determine the best PEEP, as one component of an overall safe ventilatory strategy[20] (Fig. 131.4).

As noted previously, when comparing conventional versus protective ventilation,[37] Amato attempted to control for the effect of PEEP. He used the lowest PEEP for acceptable oxygenation in the conventional group (9.3 ± 0.5 cm H_2O), while PEEP above the lower inflection point on the static pressure-volume curve was used in the protective ventilation group (13.2 ± 0.4 cm H_2O). Even though the difference in the 28-day mortality in favor of the intervention group (38% versus 71%, $p<0.001$) could have been related to the difference in PEEP, the results were criticized for the high mortality in the conventional group, and the lower tidal volume in the protective ventilation one.

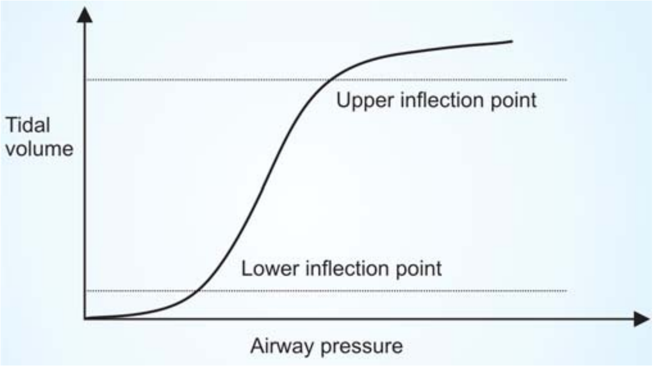

Fig. 131.4: Pressure-volume relationship of the lung. Positive end-expiratory pressure above the lower inflection point prevents the cyclic opening and collapse of alveolar units, while ventilation above the upper inflection point leads to alveolar overdistention and lung injury. Ventilation within these two points can potentially reduce the risk of iatrogenic alveolar injury

Following the Amato study, the low tidal volume ARDSnet trial used a combination of FiO_2 and PEEP designed to maintain a PaO_2 goal of 55–80 mm Hg[38] and no attempt was used to adjust the PEEP based on the pressure-volume curve. The study was therefore not designed to address the PEEP effect on mortality.

In an attempt to answer this question, the ARDS network randomized 549 patients with acute lung injury and ARDS to mechanical ventilation with low (8.3 ± 3.2 cm H_2O) or high PEEP levels (13.2 ± 3.5 cm H_2O).[44] PEEP was set according to different tables of predetermined combinations of PEEP and fraction of inspired oxygen. As with previous trials, the lower inflection point of the pressure-volume curve was not used to set the PEEP levels. Low tidal volume of 6 ml/kg was used in both groups. Survival, ventilator and intensive care unit (ICU)-free days, inflammatory cytokines and rate of hospital discharge were all similar in both groups.

More recently, a French study tried to answer the same question using a different strategy.[45] Patients with ALI, ventilated with a tidal volume of 6 ml/kg of predicted body weight, were randomized to "minimal distension strategy" versus "increased recruitment strategy". In the former, PEEP and plateau pressure were set as low as possible without falling below oxygenation targets (PaO_2 goal of 55–80 mm Hg, or an oxyhemoglobin saturation of 88 to 95%). External PEEP was set to maintain a total PEEP (external + intrinsic PEEP) between 5 and 9 cm H_2O. In the increased recruitment strategy, PEEP was adjusted based on airway pressure and was kept as high as possible without increasing the plateau pressure above 28–30 cm H_2O, regardless of its effect on oxygenation. Even though total PEEP levels were different between groups (8.4 ± 1.9 versus 15.8 ± 2.9 on day 1, $p <.001$), the mortality rates were similar (31.2% versus 27.8%, p=NS). However, the increased recruitment strategy improved lung function and reduced the duration of mechanical ventilation and that of organ failure.

Finally, an international trial assessing the use of high PEEP as part of an "open-lung" strategy in patients with ALI/ARDS,[46] resulted in no significant difference in all-cause hospital mortality or barotrauma compared with an established low tidal volume strategy.

Based on these trials, it appears that high levels of PEEP do not improve survival in patients with ARDS. Since side effects may occur with these high levels, the lowest PEEP that keeps acceptable levels of oxygenation and airway pressure may be used.

Mode of Ventilation

Traditional volume-assist control mode remains widely used in patients with ARDS, whether in daily clinical practice or in most recent large clinical trials.[38,44,45] It has the advantage of being relatively simple and easy to monitor as compared to the newer modalities. No studies have shown an outcome benefit when using newer modes of ventilation.

Airway Pressure Release Ventilation (APRV) is a relatively new modality that has been advocated to be used in ARDS. It is a pressure-targeted, time-cycled mode that shares some similarities with pressure-controlled ventilation, allowing the ability for spontaneous breathing. Studies have shown possible oxygenation benefit over controlled mechanical ventilation in patients with ARDS.[20] Others found a lower incidence of ARDS in trauma patients when ventilated with APRV.[47] However, since it can potentially increase the end-inspiratory stress[48] and therefore can cause volutrauma, more studies are needed to assess its effect on mortality before it could be recommended as a routine modality in ARDS.

Other ventilatory modalities include the use of partial liquid ventilation. Perfluorocarbon is a liquid with characteristics that makes it appealing to use in ARDS. It combines rapidly with gas ventilation and stabilizes alveoli by covering the alveolar lining.[49] It may possess anti-inflammatory properties,[50] and can shift the blood away from dependent regions of the lung.[51] Large doses can cause lung injury with pulmonary edema. Several phase I/II trials have assessed its use, but it should be considered experimental until more definitive studies are done.[20]

Recruitment Maneuvers in ARDS

Recruitment maneuvers involve the application of a high and sustained airway pressure, enough to open collapsed alveoli. This is done in the presence of sufficient PEEP application that will maintain these units open. The goal is to reverse the atelectasis and improve oxygenation. However, the effect on oxygenation has been variable, and the potential for adverse hemodynamic effects is concerning.[20] In addition, no data on outcome in patients with ARDS is available. Therefore, this maneuver cannot be routinely recommended in patients with ARDS.

Noninvasive Ventilation

The use of Noninvasive Ventilation (NIV) in hypercapnic respiratory failure has been shown to decrease the need for intubation, the length of hospital stay as well as the mortality rate.[52,53] Its effect on patients with hypoxemic respiratory failure, including ALI/ARDS, is less clear. When comparing NIV to invasive mechanical ventilation in immunocompetent patients with acute respiratory failure not due to chronic obstructive pulmonary disease, Antonelli found fewer complications and a trend toward better survival in the NIV group.[54] A similar trend toward lower mortality was also seen with bi-level positive airway pressure when compared to usual medical care in patients with hypercapnic and hypoxemic respiratory failure.[55]

When compared to the immunocompetent patients, immunosuppressed patients with ARDS/ALI are at higher mortality risk from ventilator associated pneumonia, approaching 90 to 100%.[56] Therefore, a strategy, such as NIV, that avoids invasive mechanical ventilation could theoretically reduce mortality in this population. In fact, in a randomized trial of intermittent NIV compared with standard treatment with supplemental oxygen and no ventilatory support, Hilbert et al. found that the early initiation of NIV in 52 immunosuppressed patients with pneumonitis and acute respiratory failure was associated with significant reductions in the rates of endotracheal intubation and serious complications.[57] An improved likelihood of survival to hospital discharge was also seen. Significant reduction in the rate of ventilator-associated pneumonia and sinusitis was noted, which is the likely explanation for the observed improvement in mortality.

Based on these studies, it appears that careful patients' selection is a key to success when using NIV in ARDS/ALI. One must use and consider the patients' comorbidities as well as the severity of the respiratory failure when deciding whether to institute NIV or proceed directly to endotracheal intubation with invasive mechanical ventilation.

Fluid Management/Pulmonary Artery Catheter

Fluid management in ARDS is a delicate issue. On one hand, many patients with ARDS have underlying sepsis, may have intravascular fluid deficit and/or may be they are hypotensive. On the other hand, the fact that ARDS is a normal pressure pulmonary edema means that any fluid administration has the potential to worsen the pulmonary edema, increase the alveolar flooding, and decrease the PaO_2/FiO_2. Theoretically, this is a situation where measuring the pulmonary capillary wedge pressure would guide therapy and may result in outcome improvement. Trials have suggested that those ARDS patients who achieve negative fluid balance have improved outcome.[58-60] In addition, excessive fluid administration in trauma-related ARDS patients was associated with increased mortality.[61]

In order to answer the question, the ARDS network conducted a large prospective trial comparing conservative and liberal fluid management strategies, using protocols applied for seven days in 1000 patients with ALI.[62] During the first seven days, the mean cumulative fluid balance was 136 ± 491 ml in the conservative strategy group and 6992 ± 502 ml in the liberal strategy group ($p < 0.001$). As compared with the liberal strategy, the conservative strategy improved the oxygenation index, lung injury score and the number of ventilator-free days. There was no difference in shock, use of dialysis, or in the primary outcome of 60-day mortality (Fig. 131.5). Overall, it was felt that these results support the use of a conservative strategy of fluid management in patients with ALI.

Using the same population in a 2x2 design, Wheeler et al. compared the benefits and the risks of pulmonary-artery catheters (PAC) to those of a central venous catheters (CVC) in ALI.[63] PAC-guided therapy did not improve survival or organ function but was associated with more complications than CVC-guided therapy (predominantly arrhythmias), suggesting that PAC should not be routinely used for the management of ALI (Fig. 131.6).

Other Supportive Therapies

Prone Position

The use of prone position in ARDS consistently results in oxygenation improvement.[64,65] The reason for this improvement is unclear.[20,66,67] Several possibilities have been suggested, including atelectasis reversal, alveolar recruitment, with increased lung volume, decreased shunt fraction and improved ventilation-perfusion mismatch. Other possible mechanisms include the release of the effect of the heart weight on the left lung, and better drainage and clearing of respiratory secretions.

Two recent randomized large trials evaluated the effect of prone on survival. In the first one,[68] Gattinoni randomized 304 ARDS patients to supine versus prone position for a minimum of 6 hours/day. Even though he found a significant improvement in oxygenation in the prone group, there was no difference in survival. In a larger trial enrolling 791 patients meeting criteria for ALI[69] Guerin et al. assessed the effect of prone position, used for atleast 8 hours/day. The 28-day mortality was similar to the control group. Even though the PaO_2/FiO_2 ratio was significantly higher in the prone group, this group has a higher incidence of pressure sores, selective intubation and endotracheal tube obstruction, raising safety concerns regarding this therapy.

At this point, prone position can be used as salvage therapy in ARDS patients with refractory hypoxemia.

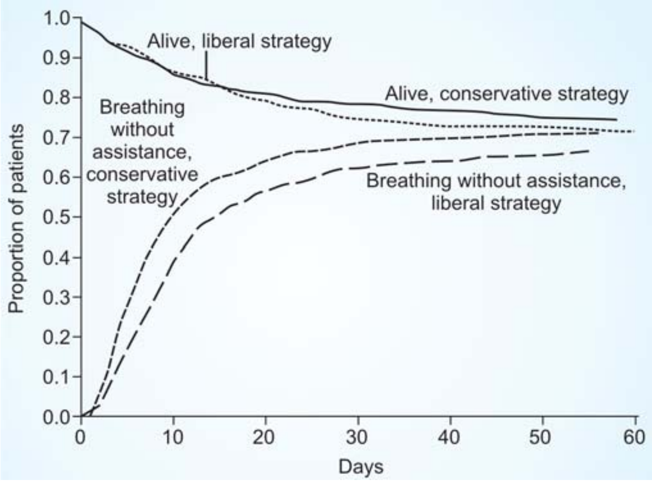

Fig. 131.5: Comparison of two fluid management strategies in ALI: Probability of survival to hospital discharge and of breathing without assistance during the first 60 days after randomization (Adapted with permission from Wiedemann et al)[62]

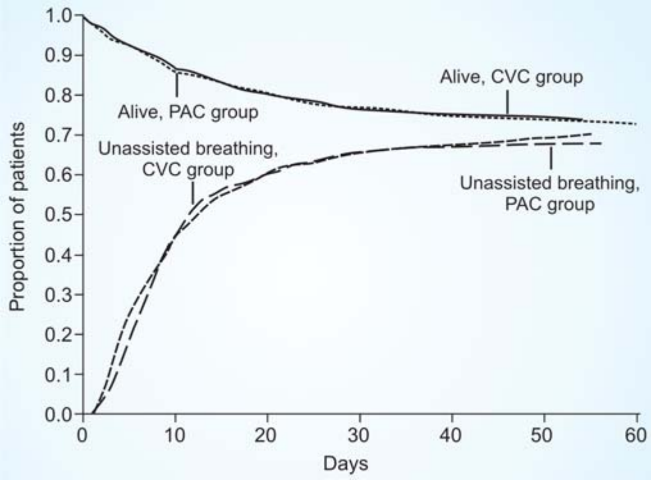

Fig. 131.6: Pulmonary artery versus central venous catheter to guide treatment of ALI: Kaplan-Meier estimates of the probability of survival and of survival without the need for assisted ventilation during the first 60 days after randomization (Adapted with permission from Wheeler et al)[63]

Current evidence do as not support its routine use in all patients with ARDS/ALI, especially that a survival benefit has not been demonstrated and the potential for side effect is concerning. Whether different approaches involving longer proning duration or better patients' selection could lead to a reduction in mortality remains an open question. Further studies are inevitably needed to try to answer it.

Inhaled Nitric Oxide (iNO)

Inhaled nitric oxide is a powerful vasodilator. When used in patients with ARDS, it has the potential to improve the ventilation-perfusion mismatching, with reduction in the pulmonary vasoconstriction and hypertension seen in those patients.[70] It is rapidly deactivated by the hemoglobin and therefore, has practically no systemic effects.[71] The effect of iNO on oxygenation is dose dependent, with maximal improvement seen between 1 and 10 parts per million (ppm).[72]

The use of iNO was evaluated in multiple clinical trials,[73,74] with some combining it with the use of prone position.[75,76] Using a low dose (5 ppm) in patients with ALI (defined as $PaO_2/FiO_2 < 250$) not due to sepsis and without evidence of nonpulmonary organ dysfunction, Taylor found an improvement in the oxygenation within the first 24 hours of therapy, an effect that was lost after two days of treatment.[73] There was no effect on mortality rate or duration of ventilatory support. Similar results were found by other investigators.[74] When combined with prone position, an additive effect on oxygenation was seen, but no firm data on survival is available.[75,76]

In clinical practice, as with any salvage therapy in ARDS, iNO may be utilized in patients with refractory hypoxemia, keeping in mind that the beneficial effect is likely to be time limited.

Surfactant Therapy

As mentioned previously, the surfactant composition and function is affected in patients with ARDS.[23,77,78] Therefore, replacement therapy is an appealing modality, with animal models showing improvement in gas exchange.[79] In addition, survival of neonates with ARDS was improved with the use of surfactant.[80]

Several studies evaluated surfactant therapy in adults with ARDS. Evaluating a nebulized synthetic surfactant in a placebo-controlled trial involving 725 patients with sepsis-related ARDS, Anzueto et al. found no effect on oxygenation, length of stay in the intensive care unit, duration of mechanical ventilation or survival. Results of this study may have been affected by the low dose used (5 mg/kg/d).[81] On the other hand, another trial showed significant and rapid improvement in the PaO_2/FiO_2 when natural bovine surfactant extract was administered bronchoscopically, also in sepsis-induced ARDS.[82] Finally, two randomized, double-blind trials involving 448 patients with ARDS from various etiologies, evaluated up to four intratracheal doses of a recombinant protein C-based surfactant given within 24 hours of enrollment.[23] Oxygenation improved significantly in the first 24 hours, but the benefit was lost after 48 hours of treatment. There was no benefit in terms of the 28-day survival or in the number of ventilator- free days.

Therefore, it appears that surfactant replacement may have the potential to improve oxygenation in ARDS, but no effect on mortality is yet demonstrated. However, more studies are needed to control for several variables, including the type of surfactant used, the route of administration (Nebulized versus bronchoscopic) and the duration of therapy.

Steroids

The use of steroids in ARDS has been one of the most controversial issues over the last several decades. As powerful anti-inflammatory agents, it is reasonable to expect some beneficial effect in such an intense inflammatory milieu.

In studies performed in the 1980s, high dose steroids in the early stage of ARDS proved to be ineffective.[83, 84] Revisiting this issue, a recent randomized, double-blind, placebo-controlled trial evaluated the use of methylprednisolone infusion (1 mg/kg/d up to 28 days) in severe early ARDS ($\leq$72 hours).[85] Treatment with steroids was associated with a reduction in the duration of mechanical ventilation, ICU stay and ICU mortality (20.6% versus 42.9%; $p=0.03$). Interestingly, treated patients had a lower rate of infections ($p = 0.0002$).

In terms of steroid use in the late proliferative phase of ARDS, several case series were reported.[86-88] In 1998, Meduri published the results of a randomized controlled trial assessing the effect of prolonged methylprednisolone (initial dose at 2 mg/kg/day, and duration of treatment of 32 days), in 24 patients with nonresolving ARDS.[89] The hospital-associated mortality was significantly lower in the methylprednisolone group (12% versus 62%, $p=0.03$). Meduri's study was criticized due to the relatively low survival rate in the placebo group.

In order to answer the question of steroids in late ARDS, the ARDS network conducted a multicenter trial comparing high-dose methylprednisolone to placebo in 180 patients. There was no survival benefit in the steroid group (29.2% versus 28.6%, p=1.0), despite a significant improvement in lung mechanics, gas exchange and ventilator-free and shock-free days. Methylprednisolone did not increase the rate of infectious complications but was associated with a higher rate of neuromuscular weakness.

Finally, a recently meta-analysis of selected trials showed that prolonged administration of systemic steroids is associated with favorable outcomes and survival benefit when given before day 14 of ARDS.[90]

In conclusion, the use of steroid in ARDS remains controversial at best. Any possible benefit should be weighted against the potential for adverse effects including infections and neuromuscular weakness.

Protein C

Activated Protein C (APC) has anti-inflammatory, antithrombotic and fibrinolytic activities.[91] Replacement in ALI was advocated after its levels were found to be decreased in patients with ALI/ARDS.[92] It was also associated with higher mortality rate and less ventilator-free days. However, a recent randomized placebo-controlled trial failed to show a beneficial effect, with no difference in the 60-day mortality or the number of ventilator-free days in ALI patients receiving placebo or APC.[93]

Prognosis and Outcome

The outcome of patients with ARDS depends primarily on the underlying cause of lung injury. Survival to home discharge appear to be lowest in patients with sepsis and highest in patients with trauma and ARDS.[8] Until recently, the mortality ranged from 40 to 60%, with the majority of deaths being related to sepsis and nonrespiratory organ dysfunction.[5] More recent reports suggest that the mortality may be decreasing.[38,44,45,94] Reasons for this improvement are not entirely clear, but are likely related to the use of low tidal volume, better supportive care and better management of sepsis.

Predictors of death include chronic liver disease, nonpulmonary organ dysfunction, age and sepsis. Initial oxygenation and ventilation indices do not predict outcome.[5]

Even though the 28-day mortality has been a traditional primary end-point in studies of ARDS, following patients for up to 1 year shows that a significant percentage of deaths actually occurs beyond the 28-day cutoff,[95] raising the potential need for longer monitoring when evaluating new interventions or therapies. Anxiety, depression and posttraumatic stress disorder were frequent in this study, while predictors of mortality included age, sepsis, extrapulmonary organ failure and the premorbid functional status. In addition, patients with ARDS lose a significant amount of weight during their hospitalization, averaging around 18%.[96] Most recover their weight gradually, but remain below their admission weight at 12 months. Proximal muscle weakness and a decrease in 6-minute walk test are common. Radiographic abnormalities remain present in 80% of cases at 12 months. Mild restrictive pattern is seen at three months, gradually improving with most values back within normal limits at 12 months. Oxygen requirement is uncommon after 12 months.

Longer follow-up showed that ARDS can result in significant neurocognitive and emotional morbidity and decreased quality of life that persists at least two years after hospital discharge.[97]

CONCLUSION

ARDS continues to be one of the major challenges facing modern critical care medicine in the 21st century. Major advances have been achieved in the last few years in terms of understanding the syndrome, but translating this knowledge into improved outcome has proved more challenging than initially thought. Except for the low tidal volume strategy, no intervention was shown to be unequivocally effective in reducing mortality. Nevertheless, several salvage therapies are available (e.g. iNO, prone position, etc.), with relatively good impact on oxygenation. One should use them only in patients with refractory hypoxemia and even though the quality of clinical trials has improved over the last decade, further studies are still needed to advance our understanding of this syndrome and to translate that understanding into reduced morbidity and mortality.

Sepsis

Sean E Hesselbacher, Kalpalatha K Guntupalli

INTRODUCTION

Sepsis has been acknowledged as an entity since the time of Hippocrates. Without knowing of the cause of sepsis, or even the significance of the accompanying fevers, early treatments had little chance. Progress made by scientists in the 19th and early 20th centuries provided a new therapeutic target when they discovered the link between microorganisms to sepsis, though the impact remained unacceptably high despite the use of antibiotics. Throughout the 20th century, our knowledge of sepsis proliferated with the understanding that its deadly nature was not necessarily due to the illness-causing pathogens, but the disproportionate inflammatory response of our own immune systems to those pathogens. We then understood that the mechanisms that protected us from overwhelming infection on a daily basis could be turned against us to cause organ failure and death. Unfortunately, attempts to alleviate the devastating effects of sepsis with the use of powerful immunosuppressants did not have the impact we had hoped for.

Today, despite rapidly advancing research about the mechanisms of sepsis and septic shock, it remains a leading cause of death. We now have a vast armamentarium of weapons against sepsis, from simple hydration and antibiotics to medications directed at molecular targets. Yet the burden of sepsis remains unacceptably high and it is highest in parts of the world where resources may be limited, without access to the newest treatments. The good news is that many of the therapies directed at reducing mortality due to sepsis are readily available and effective when used in the appropriate manner. Most recent research suggests that an organized, systematic approach to the diagnosis and treatment of sepsis is the key to success. In that light, many suggested guidelines exist, which can be altered to suit the needs and resources of developing countries.

Definition

The term *sepsis* is derived from the Greek word for "putrefaction".[1] Our first recorded uses of the word come from Hippocrates, Aristotle and the poet Homer.[2] As our understanding of the process behind the word changed, so did the definition of the word. In 1914, we were introduced to the concept that had guided our ideas about sepsis over the past century: the systemic symptoms of sepsis were due to pathogens in the bloodstream.

The most commonly used definition of sepsis came from a consensus conference sponsored by the American College of Chest Physicians (ACCPs) and the Society of Critical Care Medicine (SCCM) in 1992.[3] Four important definitions were presented from this conference: the Systemic Inflammatory Response Syndrome (SIRS), sepsis, severe sepsis and septic shock (Table 132.1); additionally the concept of the Multiple Organ Dysfunction Syndrome (MODS) was introduced. As the name suggests, SIRS constitutes the systemic inflammatory response, due to infection, trauma, burns or other causes. The term sepsis is used to describe SIRS that is due to an infection. Noninfectious SIRS can progress similarly to sepsis, but is treated differently, so will not be discussed here. When sepsis progresses to cause organ dysfunction, hypo-perfusion or hypotension, it is severe sepsis. The final stage in the progression of sepsis is septic shock, which is sepsis-induced hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities. The natural progression of severe sepsis and septic shock lead to irreversible organ failure and death. These definitions remain widely used in both clinical medicine and research settings, though the sponsoring organizations have abandoned them as obsolete.

In 2001, the ACCP and SCCM joined with the European Society of Intensive Care Medicine, the American Thoracic Society, and the Surgical Infection Society to update the definitions.[4] This scheme maintains a similar structure, referring to SIRS, sepsis, severe sepsis and septic shock (Table 132.1). The major update is a much broader definition of SIRS to more closely reflect the experience of the bedside clinician caring for a patient that "looks septic". The new list of signs and symptoms includes many more physical examination and laboratory findings than in the previous definition. This updated version is less useful for research purposes, since the definitions are more imprecise, but designed to assist the practicing clinician. The new definition of sepsis also does not require an infection to be confirmed if it is strongly suspected clinically. The definitions of severe sepsis and septic shock remain essentially unchanged. A staging system, intended to be used to stratify patients based on their baseline risk for adverse outcomes and their potential to respond to therapy. It is known as the PIRO system, which stands for Predisposition, Insult or Infection, Response, and Organ dysfunction. While useful in certain circumstances, the staging system has not gained the same popularity as the classification structure listed in Table 132.1.

Epidemiology, Outcomes and Costs

The impact of sepsis throughout the world is costly in the terms of lives lost and the financial burden on the society. Many of the recent studies examining the epidemiology of severe sepsis and septic shock have been based in the United States,[5,6] Europe,[7-11] or Australia/New Zealand.[12] Based on these studies, the estimated incidence of sepsis is 50–100/100,000 of these populations, though the most recent of these studies[11] reported an incidence of 25/100,000 in a limited Spanish population. The absolute incidence of sepsis in the US is estimated to be 750,000 cases per year. Severe sepsis and septic shock accounted for 12 to 27% of intensive care unit (ICU) admissions in these studies, and mortality rates ranged from 35 to 56% at one month. The mean ages reported were 59–65, and infection was confirmed with positive cultures in less than 75% of the cases. The incidence of sepsis is expected to rise in the years to come, due to the practice of performing more invasive procedures and increased immunosuppression.

The epidemiology of sepsis in developing countries is less defined. Two recent studies have investigated the incidence, outcomes and costs of sepsis in Brazil.[13,14] The incidence density of all categories of sepsis in five ICUs was calculated as approximately 57 per 1,000 patient days, which was generally higher than that reported in industrialized nations. The mean age of patients with sepsis was similar to the other studies. The respiratory tract was the most common site of infection. The mortality rates for patients with sepsis, severe sepsis and septic shock were 34, 47 and 52%, respectively. The median daily ICU cost of a septic patient in Brazil was found to be $934 US. Interestingly, despite similar total costs, length of hospital stay, and admission illness severity, patients at private hospitals had significantly better mortality rates than those at public institutions.

The World Health Organization[15] does not specifically track sepsis statistics. However, there is data regarding the epidemiology and outcomes of infectious diseases overall. While it is impossible to separate the specific causes of morbidity or death due to infectious diseases (as severe diarrhea may lead to dehydration or meningoencephalitis may cause a CNS insult without systemic inflammation), these numbers can give us a general idea of the relative impact sepsis may have in developing areas of the world. Figures 132.1A and B show the incidence of infectious diseases (excluding HIV seropositivity), and the morbidity and mortality due to those infectious diseases. While the overall numbers do not appear remarkably different relative to one another, simple calculations reveal that the death rate per infection is higher in low and lower-middle income countries (1 in 436) than the worldwide rate (1 in 453), and the rate in the Southeast Asia Region (SEAR) (1 in 379) is even higher than that. The significance of this statistic is unclear, though if sepsis is considered to be a major contributor to these deaths, limited resources presumably play a role in the higher mortality rate.

Pathogenesis

By definition, sepsis is the result of one or more pathogens invading the body and causing infection. The most common causes of sepsis worldwide are bacterial agents (93%). Sepsis can also result from viruses, fungi and protozoa (Table 132.2); in fact, almost any pathogen that causes infection can result in sepsis. When considering the likely etiology of sepsis in an individual patient, it is important to consider the prevalent

TABLE 132.1: Definitions of sepsis

*1992 Consensus Committee**	*2001 International Sepsis Definitions Conference*[†]
SIRS Two or more of the following in response to an insult: 1. Temperature >38°C or <36°C 2. HR >90 beats per minute 3. RR >20 breaths per minute or PaCO$_2$ <32 mm Hg 4. WBC count >12,000 per mm^3 or <4,000 per mm^3 or >10% immature band forms	SIRS "Some" of the following: 1. General variables a. Core temperature >38.3°C b. Core temperature <36°C c. Heart rate >90 per minute d. Tachypnea e. Altered mental status f. Significant edema or positive fluid balance (>20 mL/kg over 24 hr) g. Plasma glucose >120 mg/dL in the absence of diabetes 2. Inflammatory variables a. WBC count >12,000 per μL b. WBC count <4000 per μL c. Normal WBC count with >10% immature forms d. Plasma C-reactive protein >2 SD above the normal value e. Plasma procalcitonin >2 SD above the normal value 3. Hemodynamic variables a. Arterial hypotension (SBP <90 mm Hg, MAP <70, or an SBP decrease >40 mm Hg) b. SvO$_2$ >70% c. Cardiac index >3.5 L/min/m^2 4. Organ dysfunction variables a. PaO$_2$/FIO$_2$ <300 b. Urine output <0.5 mL/kg per hr for at least 2 hr c. Creatinine increase >0.5 mg/dL d. INR >1.5 or aPTT >60 sec e. Absent bowel sounds f. Platelet count <100,000 per μL g. Plasma total bilirubin >4 mg/dL 5. Tissue perfusion variables a. Lactate >1 mmol/L b. Decreased capillary refill or mottling
Sepsis The systemic response to infection: 1. SIRS and 2. Documented infection	Sepsis 1. SIRS and 2. Documented or suspected infection
Severe sepsis Sepsis associated with organ dysfunction: 1. Sepsis and 2. One of the following: a. Sepsis-induced hypotension (SBP <90 mm Hg or reduction by ≥ 40 mm Hg from baseline in the absence of other causes of hypotension) or b. Lactic acidosis or c. Oliguria or d. Acute alteration in mental status	Severe sepsis Sepsis complicated by organ failure: 1. Sepsis and 2. Organ dysfunction (see SIRS 4)
Septic shock Severe sepsis and one of the following despite adequate fluid resuscitation: 1. Sepsis-induced hypotension (see Severe sepsis 2a) 2. Requirement of vasopressor or inotropic therapy	Septic shock Acute circulatory failure due to sepsis: 1. Sepsis and 2. Persistent arterial hypotension (see SIRS 3a) despite adequate volume resuscitation and 3. No other cause of hypotension

pathogens in the region, the setting in which the infection was acquired (outpatient, hospital or ICU), and host factors, including immunosuppression, comorbidities, medications, lifestyle and travel. All of these factors will narrow or broaden the list of potential causative agents. It is clear from Figure 132.1 that the vast majority of infections do not lead to significant morbidity or death. There are clearly host abnormalities, which lead to sepsis that do not depend entirely on the invading organism. The expression of toxins from invading pathogens, such as lipopolysaccharide (LPS) or staphylococcal toxic shock syndrome toxin 1 (TSST-1), or release of molecules from damaged host tissues are thought to act as triggers for sepsis. These molecules are known as damage-associated molecular patterns (DAMPs) and are recognized by toll-like receptors (TLRs) on neutrophils, macrophages and other innate immune cells.[16] Early sepsis is characterized by the activation of $CD4^+$ Th1 cells and the release of proinflammatory mediators, leading to systemic inflammation and SIRS.

The propagation of sepsis is complicated, involving multiple systems and pathways (Fig. 132.2), with resulting end-organ damage.[16-18] Innate immune cells also activate complement C5a, with the resulting activation of the complement cascade. The complement cascade not only augments the inflammatory response, but is also involved in a complex feedback loop with both the intrinsic and extrinsic coagulation pathways. The

Fig. 132.2: **The pathologic immune response in sepsis.** Sepsis is initiated by molecules expressed by pathogens and released by damaged host tissue, which stimulate the innate immune cells (neutrophils, macrophages, monocytes and dendritic cells). The early response of sepsis is characterized complex interactions between the proinflammatory adaptive immune system, complement cascade, and the intrinsic and extrinsic coagulation cascades. The late response is characterized by an anti-inflammatory response by the adaptive immune system, and immune cell dysfunction and apoptosis, resulting in an immunosuppressed state.

DAMP: damage-associated molecular patterns; Th1 and Th2: T helper lymphocytes, subtypes 1 and 2; $CD4^+$: expression of CD4 glycoprotein surface marker; PMN: polymorphonuclear lymphocytes or neutrophils; SIRS: systemic inflammatory response syndrome; DIC: disseminated intravascular coagulation; iNOS: induced nitric oxide synthetase.

coagulation cascades themselves are activated by the damaged tissues that triggered the sepsis in the first place, and uncontrolled activation results in microvascular thrombosis, inhibited fibrinolysis, and disseminated intravascular coagulation (DIC). Activated thrombin can promote the inflammatory pathway, providing another feedback loop. Unchecked systemic inflammation increases intrinsic nitric oxide synthetase activity in endothelial cells, resulting in arterial vasodilation and hypotension. This hypotension is initially counteracted by the release of catecholamines by adrenergic cells. Catecholamines also function to further activate leukocytes. Conversely, the stimulation of the vagus nerve will suppress inflammation through the activation of nicotinic acetylcholine receptors on macrophages. The result of the combination of systemic inflammation, cytokine storm, arterial hypotension, and DIC is often multiple organ dysfunction and failure.

The late phase of sepsis is characterized by immunosuppression. Previously activated Th1 cells evolve into $CD4^+$ Th2 cells, with the production of anti-inflammatory cytokines. Persistent inflammation and activation of the complement cascade result in apoptosis of immune cells, neutrophil dysfunction, hypothermia and anergy. In the immunosuppressed state, the host is no longer able to fight off infection and is susceptible to nosocomial infections. Apoptosis also occurs in other systems, including the adrenal medulla. As adrenal medullary cells are lost, catecholamine function decreases and arterial hypotension becomes more pronounced. A similar process may also lead to adrenal insufficiency. As the sepsis resolves, the immunosuppressed state will eventually recover. In patients with severe baseline comorbidities however, the immunosuppression may progress, with resulting death.

Clinical Features and Evaluation

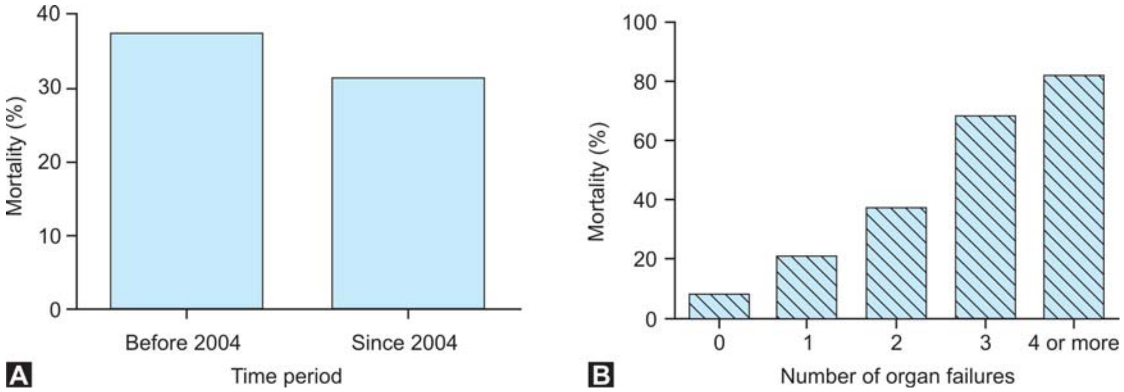
The patient with sepsis will often present with the symptoms of SIRS. The signs of SIRS are summarized in the report from the 2001 International Sepsis Definitions Conference (see Table 132.1). In general, these patients may complain of fever or chills, fatigue, malaise, anorexia, and sometimes complaints specific to the source of infection. Whether or not there are complaints reflecting organ dysfunction, such as confusion or poor urine output, the clinician must always be aware of these signs, which can reflect progressing sepsis. Physical examination findings should always begin with vital signs and a general impression of the patient. Septic patients will show vital signs reflective of SIRS, including fever or hypothermia, tachycardia, tachypnea, and possibly hypotension. In the general impression, there will be useful information that can provide a snapshot of the patient's overall condition, as well as the premorbid status. This impression will be important in assessing the level of care a patient will require; be aware that some patients' general appearance may not reflect the true extent of their illness. The remainder of the physical examination will vary, depending on the source of infection. The physical examination may be unrevealing in this regard, especially in the elderly or immunocompromised patient population, so laboratory and imaging must be relied on.

Basic laboratory data can help in the diagnosis of sepsis and organ dysfunction. These basic investigations should include a complete and differential blood counts, chemistry panel, including glucose, liver function tests and coagulation tests. Other diagnostic tests may be clinically indicated for initial diagnosis, including serum C-reactive protein, procalcitonin and serum lactate. Work-up to determine the source of sepsis will be directed by the patient history and physical examination, and may include urinalysis, chest and/or abdominal imaging, and lumbar puncture, depending upon the clinical situation.

Physical examination and laboratory evidence of organ dysfunction and failure will be seen in a significant proportion of septic patients. Any organ system can show the effects of sepsis, and mortality increases with the number of organ systems affected. Table 132.3 provides a summary of some of the findings that can be seen in organ system dysfunction. In cases where specific treatments are available, the appropriate clinical evaluation should be undertaken.

Cultures will ideally be drawn prior to the initiation of antibiotics, but only if it will not delay the dosing of antibiotics. Cultures should be taken from the blood and from the presumed site of infection. If the site of infection is unknown, cultures from multiple sites may be taken, which may eventually reveal the source. A minimum of the two sets of blood cultures can be obtained, at least one from each vascular access catheter in place. If the source is an abscess, deep tissue infection, or a mechanical device, cultures can be sent from the surgical or drainage specimens, once obtained. The rate of microbiological confirmation of infection has been reported to be in the range of 58 to 76%,[11,12,19-21] so the diagnosis of sepsis should not be discounted if infection is still strongly suspected.

More invasive monitoring may be indicated in the cases of severe sepsis or septic shock to guide therapies. Arterial blood gas assessment is required in patients with



Figs 132.3A and B: Predicted mortality rates due to sepsis. (A) The overall mortality rate due to sepsis has decreased since the launch of the Surviving Sepsis Campaign in 2004, in those adhering to the established protocols for the treatment of sepsis. (B) Predicted mortality due to sepsis and septic shock, based on the number of failed organs or organ systems

acid-base disorders and more frequently in mechanically ventilated patients. Patients with hypotension will most likely need invasive blood pressure monitoring, which may require arterial catheterization. Central venous and pulmonary artery catheterization may also be required to monitor the mixed venous (SvO_2) or central venous ($ScvO_2$) oxygen saturation, or Central Venous Pressure (CVP).

Prognosis

The prognosis of sepsis, uncomplicated by organ dysfunction or septic shock can be cause for optimism. With progression of sepsis to severe sepsis and septic shock portends escalating mortality. The severity of a septic episode is often graded by the number and type of organ dysfunction or failure.[4,22-25] There is a mortality risk associated with most individual organ failures (Table 132.3), which may or may not improve with specific treatment.[20,26-42] Additionally, studies have consistently shown an escalating mortality rate associated with a higher number of concurrent organ system failures (Figs 132.3A and B), suggesting that Multiple Systems Organ Failure (MSOF) may represent a final common pathway leading to death.

Likewise, the baseline health characteristics of an individual patient play an important role in that patient's ability to recover from a serious insult. One theory suggests that a healthy, young patient with sepsis will mount a strong immune response, followed by a transient hypoimmune state, and then recovery. Meanwhile, a septic elderly patient with multiple pre-existing dysfunctional organs will only mount a minimal inflammatory response, with a prolonged immunodepressed state, possibly followed by death.[17]

Multiple ICU scoring systems have been developed to assist the clinician in medical evaluation and treatment decisions in critically ill patients[22-24,43,44] (Table 132.4). The APACHE II remains perhaps the most widely used scoring system, mostly due to the vast literature based on this system and the availability in the public domain free of cost. The scoring system assigns points for 12 acute physical examination or laboratory findings, as well as age and chronic health; the higher the sum of the points, the higher the predicted mortality.[43] The APACHE II score is currently recommended to determine the suitability of potentially harmful treatments in septic patients.[45] Other scoring systems, such as the MODS and SOFA systems each assign points (0–4) based on the degree of acute dysfunction in six systems. Again, higher sums predict higher mortality. Other scoring systems also exist for use in septic patients, each with advantages and disadvantages.

Management

As demonstrated in Figure 132.1, the multiple cascades responsible for the propagation of sepsis are intertwined to the point that the interruption of the process, once started, is nearly impossible with a single therapy. The ideal treatment would target a common pathway or several pathways at once. More practical is the use of several agents at the same time, in a strategic manner, to stop or slow the progression at several key points. The past decade has produced significant advancement in the development of the systematic protocols necessary for the effective management of sepsis.

TABLE 132.3: Organ systems affected in severe sepsis and septic shock

Organ system	*Clinical manifestations*	*Associated mortality*	*Management (in addition to supportive care)*
Nervous system	Encephalopathy	24%	Sedation, stimulus control
	Critical illness neuromyopathy	21-55%	Avoid aggravating medications (neuromuscular blockade, corticosteroids)
Respiratory	ALI, ARDS, hypoxemic respiratory failure	21-47%	Oxygen, mechanical ventilator support
Cardiovascular	Hypotension, tachycardia	28-43%	Vasopressors, inotropes, mechanical CV support
	Myocardial injury and dysfunction	29-48%	
Kidneys	Olig- or anuric AKI	15-46%	Electrolyte management, renal replacement therapy
Hematologic	Cytopenias	23-53%	Blood product transfusions
	Coagulopathy	17-51%	
	Microvascular thrombosis/DIC	43-50%	Activated protein C
Gastrointestinal	Shock liver, acute hepatic failure, hyperbilirubinemia	14-54%	Avoidance of hepatotoxic agents
	Ileus	Not defined	Bowel rest, parenteral nutrition
Endocrine	Hyperglycemia	22-53%	Insulin
	Adrenal insufficiency	25-80%	Glucocorticoids
	Thyroid hormone abnormalities	44-62%	Generally none (in sick euthyroid), other abnormalities may require specific treatment
Skin	Rash, wounds	Varies by cause	Wound care, prevent superinfection

TABLE 132.4: Scoring systems applicable to sepsis

Scoring system	*Description*	*Advantages*	*Disadvantages*
GCS (Glasgow Coma Score)	Neurologic scale (3-15) to assess level of consciousness	Simple; applicable to all trauma and medical patients; used in other scoring systems	Single organ system
APACHE II (Acute Physiology and Chronic Health Evaluation)	Calculated (0-71) within 24 hrs of admission using common physiologic and demographic data, and prior health status	Widely used; online scoring systems; can assist in treatment decisions	Imprecise in predicting the mortality of a single patient; revised (APACHE III) in 1991
SOFA (Sepsis-related / Sequential Organ Failure Assessment)	Calculated (0-24) based on degree of organ failure in 6 systems	Can be calculated sequentially in the same patient	Multiple possible comparisons (admission, maximum, change in maximum), not one standard
MOD (Multiple Organ Dysfunction) score	Calculated (0-24) based on degree of organ failure in 6 systems	Can be calculated sequentially in the same patient	Complicated CV measures; similar to but less prevalent than SOFA
SAPS II (Simplified Acute Physiology Score)	Calculated on 17 variables after 24 hours, using common physiologic and demographic data and prior health status	Can be used in a variety of diseases; compare the morbidity of a patient/group to others	Imprecise in predicting the mortality of a single patient; revised (SAPS III) in 2005

Antibiotics and Infection Source Control

The effective use of proper antibiotics is the only therapy that can truly stop sepsis before it gets going. Antibiotics, if given early, will either destroy or halt the replication of the pathogen, and in some cases will also absorb the toxins released. The antibiotic selection must be appropriate for the clinical situation, however. Several studies have examined the effect of the initial antibiotic regimen in septic patients.[46,47] In all cases, mortality was increased in patients that had delays in getting appropriate antibiotics for the pathogen that was eventually isolated. In the septic population, the appropriate initial antibiotic is any antibiotic that will target the causative pathogen. There are few cases where the microbiologic answer is available immediately. A suggested strategy is to administer a regimen of antibiotics that will broadly cover most, if not all, of the microbes to which the individual patient is at risk, based on medical history, personal habits, and the endemic pathogens. Once the organism has been isolated, the antibiotics can be titrated as appropriate. Rapid identification of the organism may be accomplished by examining a stain, such as a Gram stain, of the body fluid, later confirming the isolate with culture.

In some cases, antibiotics alone will not be enough to clear the infection without additional intervention. Some examples of this scenario include abscess formation, deep-seated skin/soft tissue infections, and infected mechanical devices. Abscesses may be present in a septic patient with no identifiable source of infection. Drainage of the abscess may be needed to clear the infection completely. Likewise, deep-seated infections often require debridement. In these cases, the appropriate intervention should be considered, provided the clinical situation allows for such a procedure. Mechanical devices sometimes present a therapeutic dilemma. Every attempt should be made to remove the infected foreign body from the patient, allowing the antibiotics to clear the infection, though that approach is not always practical. In such circumstances, improvisation is necessary, often requiring long-term treatment and close monitoring. Intravascular access devices should also be removed, especially in the case of documented bloodstream infections.

Hemodynamic Support and Monitoring

Sepsis-induced hypotension is caused by a number of factors, which result in intravascular hypovolemia and arterial vasodilation. The goal of correcting hypotension is to maintain adequate tissue perfusion. Tissue perfusion can be assessed by serum lactate, end-organ function, and SvO_2 (SvO_2 can be approximated by $ScvO_2$ minus 5%). Lactate clearance and $ScvO_2$ are similar in demonstrating tissue hypoperfusion and guiding treatment decisions.[48] If there is evidence of hypotension or tissue hypoperfusion, aggressive rehydration should be initiated immediately. In septic patients, intravenous fluid administration is the method of choice to achieve rehydration. Isotonic crystalloid solutions, such as normal saline or lactate Ringer's solution, have been shown to be as safe and effective as colloid solutions, such as albumin, dextran or hydroxyethyl starch, in critically ill patients.[49,50] Additionally, there has not been any difference demonstrated between various crystalloids or between any of the colloid solutions.[51] As soon as tissue hypoperfusion is documented, intravenous (IV) crystalloids should be administered in bolus fashion, 20 mL/kg or 500–1000 mL (or the colloid equivalent) over 20–30 min each, to achieve a CVP of 8–12 cm H_2O (12–15 cm H_2O if mechanically ventilated).

If the blood pressure remains low (MAP <65 mm Hg) after adequate fluid resuscitation, vasopressor therapy is indicated. The agents of choice in septic shock are dopamine and norepinephrine. Both agents activate catecholamine receptors, can be titrated to achieve a goal MAP ≥65 mm Hg, and are equally effective in septic shock.[52,53] These vasopressors can be used concurrently if the primary medication is at its maximum dose. Second line agents include phenylephrine, vasopressin and epinephrine. Phenylephrine and epinephrine also work at the catecholamine receptors. Vasopressin works through a unique mechanism and functions well as an adjunct to catecholamine pressors, especially in catecholamine-resistant septic shock.[54]

In patients that still have evidence of tissue hypoperfusion despite achieving adequate arterial blood pressure through fluid resuscitation and vasopressor therapy, there remain a few strategies to improve tissue perfusion. Anemia is often concurrent with sepsis. Transfusion of red blood cells to achieve a goal hematocrit ≥30% will augment the oxygen carrying capacity of the blood that is able to perfuse the tissues. Dobutamine also has a role in this circumstance, as either dobutamine or epinephrine will provide inotropic support, improving cardiac output.[55]

Ventilatory Support

Respiratory failure is common in sepsis. This may be due to the inability to maintain supraphysiologic ventilation, which is a result of high metabolic requirement or as a compensation mechanism for metabolic acidosis. Alternatively, hypoxic respiratory failure may develop due to acute lung injury, as a direct result of infection or indirectly from the sepsis syndrome. These patients often require invasive ventilation, adhering to low tidal volume and high positive end-expiratory pressure lung-protective strategies developed for Acute Respiratory Distress Syndrome (ARDS).[56] Because sepsis tends to progress initially, patients with respiratory failure rarely resolve with Noninvasive Positive Pressure Ventilation (NIPPV) alone. In fact, the use of NIPPV is generally contraindicated in respiratory failure due to septic shock, except in special circumstances. Because sepsis increases the ventilatory requirements in these patients, standard weaning parameters may be insufficient. Discontinuation of positive pressure ventilation may not be successful until other organ failures have begun to resolve, acid-base disturbances have corrected, and vasopressors have been weaned.

Glucose Control

Hyperglycemia alone portrays increased mortality in critically ill patients,[38, 39] and intensive insulin therapy has been shown to improve mortality in a surgical ICU population.[57] Proposed benefits of glucose control include prevention of immune dysfunction, reduction of systemic inflammation, endothelial protection, and preservation of mitochondrial structure and function, all of which are important in sepsis. When medical ICU patients only have been studied, the results are less clear. At best, intensive insulin therapy did not improve mortality in medical ICU populations,[40] in particular in septic patients receiving concurrent corticosteroids.[58] At worst, intensive insulin therapy increased episodes of severe hypoglycemia and mortality in a mixed population of medical and surgical ICU patients.[41] In these studies, intensive insulin therapy involved continuous infusion of insulin, with the goal blood sugar of 80–100 mg/dL. Conventional insulin therapy was defined differently in some cases, but often involved continuous infusion, with blood sugar goals set to either 180–200 mg/dL or <180 mg/dL. While it is generally accepted that blood sugar control is important in critically ill patients, tight blood sugar control may be harmful in septic patients. Based on current literature, the goal of treatment should be to keep the blood sugar <180 mg/dL.

Corticosteroids

The use of corticosteroids in the treatment of sepsis has had a long and complex history, yet its use remains controversial. Corticosteroids were used in very high doses in the 1970's for the treatment of severe infection, with some reported benefit in hemodynamics and oxygen delivery.[59] Two large randomized, controlled studies reported in 1987 demonstrated no benefit of high-dose methylprednisolone (30 mg/kg initial dose) to patients with sepsis.[60, 61] The concept of relative adrenal insufficiency in septic shock was introduced, and several studies have since evaluated the efficacy of lower dose corticosteroids (hydrocortisone 200–300 mg/day). Relative adrenal insufficiency predicts higher mortality in septic shock.[20,26,27] A multicenter trial in 2002 demonstrated a mortality benefit among a subgroup of septic shock patients that demonstrated an inadequate response to an Adrenocorticotropic Hormone (ACTH) stimulation test (post-ACTH serum cortisol increase >9 μg/dL over baseline), though there appeared to be a trend toward decreased mortality in all subjects with vasopressor-unresponsive septic shock.[62] The use of fludrocortisone as an adjunct to hydrocortisone is not recommended, since hydrocortisone also has minera-locorticoid activity, and a recent study did not show a benefit with the use of fludrocortisone used in this manner.[58] Another recent trial did not show a mortality benefit among subjects with septic shock or the subgroup of ACTH nonresponders.[63] Given these conflicting results, hydrocortisone (200–300 mg/day, divided into 3–4 doses daily) may be used in septic shock complicated by hypotension refractory to vasopressors. ACTH unresponsiveness is not necessary to justify the use of hydrocortisone.

Activated Protein C

Functional endogenous protein C is deficient in some septic patients, which has a profound effect on the progression of sepsis and the development of organ failure.[18,64] The use of recombinant human-activated protein C (rhAPC, drotrecogin alfa) has been advocated in the most severe cases of sepsis. Among the numerous mechanisms by which activated protein C reduces the complications of sepsis are by blocking thrombin production, decreasing phagocyte chemotaxis and adhesion, inhibiting tissue factor and proinflammatory cytokines, minimizing apoptosis of lymphocytes and endothelial cells, and inhibiting the suppression of fibrinolysis.[21,64] Several studies have been done over the past decade, demonstrating a mortality benefit in severe sepsis and septic shock with single or multiple organ failure.[21,65,66] As expected by its mechanism of action, patients administered drotrecogin alfa have an increased risk of serious bleeding events, including intracranial hemorrhage and gastrointestinal (GI) bleeding, so it should not be used in patients at risk for hemorrhage, recent surgery, or anticipated need for surgery. A follow-up study specifically evaluated the use of rhAPC in patients with the low risk of death (APACHE II score <25 or single organ failure), finding no benefit.[45] Given the risk of serious bleeding complications and lack of efficacy in the low-risk population, this medication should only be used as an adjunct to the proven therapies described previously, in the patients at highest risk of death, without bleeding risk. The formal indications for use of drotrecogin alfa in the US and Europe reflect similar views.

Standardized Protocols

Perhaps the most important development over the past decade is the refinement of protocols, or quantitative resuscitation strategies, regarding the evaluation and management of sepsis. The creation of standard definitions of sepsis, severe sepsis and septic shock[3, 4] allowed for the introduction of these protocols, similar to those now prevalent in many other areas of medicine. An "early goal-directed therapy" protocol was created for a single center for severe sepsis and septic shock.[19] In this protocol, patients meeting set criteria for severe sepsis and septic shock were monitored closely in the emergency room for six hours, undergoing a sequence of measures (volume resuscitation, vasopressors, red blood cell transfusion, and dobutamine) aimed at improving tissue perfusion, as defined by a goal $ScvO_2 \geq 70\%$. The protocol resulted in an absolute reduction in 28-day mortality of 16%; similar results and reduction in ICU usage were noted when the protocol was translated into clinical practice.[67] Since, that time numerous studies have reported mortality improvement and cost reduction when similar protocols were implemented.[68-73] A recent meta-analysis found reduced mortality with the early application of quantitative resuscitation strategies to septic patients.[74]

The Surviving Sepsis Campaign was launched in 2004 with a reported goal of reducing global mortality from severe sepsis by 25% by 2009. The campaign was a collaboration of the ESICM, the International Sepsis Foundation (ISF) and the SCCM. Guidelines were released in 2004 and updated in 2008,[75,76] providing evidence-based guidelines for the diagnosis and management of sepsis. More practical bundles for sepsis resuscitation (first 6 hours) and sepsis management (first 24 hours) were also developed and distributed, and a database was created to track outcomes (Table 132.5).[77] Analysis of the database indicates that compliance with the sepsis bundles is associated with improved mortality.[78] Many hospitals have created their own sepsis protocols, based on the evidence in the literature and their own unique circumstances. Otherwise the Surviving Sepsis Campaign bundles can be adapted for the purposes of an individual institution.

TABLE 132.5: Sepsis bundles from the surviving sepsis campaign‡

Sepsis resuscitation bundle

To be completed within six hours of the identification of severe sepsis

- Measure serum lactate
- Obtain blood cultures prior to antibiotic administration
- Administer broad-spectrum antibiotic within three hours of ED admission and within one hour of non-ED admission
- Treat hypotension and/or elevated lactate with fluids
  - Deliver an initial minimum of 20 mL/kg of crystalloid or an equivalent
- Apply vasopressors for ongoing hypotension
  - Maintain MAP >65 mm Hg
- Maintain adequate CVP and $ScvO_2$ if persistent hypotension (septic shock)
  - Achieve CVP >8 mm Hg
  - Achieve $ScvO_2$ >70% or SvO_2 >65%

Sepsis management bundle

To be completed within 24 hours of presentation

- Administer low-dose steroids for septic shock in accordance with a standardized ICU policy
- Administer rhAPC in accordance with a standardized ICU policy
- Maintain glucose control lower limit of normal, but <180 mg/dL
- Maintain a median inspiratory plateau pressure <30 cm H_2O for mechanically ventilated patients

Goals of Care

As described earlier, severe sepsis often affects debilitated individuals, with numerous comorbidities that increase expected mortality from the sepsis episode. It is vital to have open discussions with the patient (if possible) and caregivers regarding the severity of illness, likely outcomes and treatment recommendations. Though it remains the responsibility of the physician to determine a reasonable plan, patient autonomy must be respected and the patient may accept or decline any treatment.[79] Depending on the clinical situation, it may be appropriate to offer palliation to the patient for the sole purpose of relieving suffering, especially if the expected mortality is unacceptably high. Frank discussions, early and often, with the patient and caregiver may minimize suffering for the patient, as well as anxiety and depression in the caregiver.[80]

Considerations for Developing Countries

As shown earlier (Fig. 132.1), the mortality rate due to infection is higher in developing regions of the world than in high-income countries. One study done in India, evaluating mortality in patients with acute respiratory failure,[25] demonstrated a higher mortality per organ failure (excluding respiratory) than shown in Figure 132.3, with the exception of four organ failures (only one case in the study). Another study done in Kathmandu on a young patient population (mean age 34 years) with SIRS showed an overall mortality of 40% in the ICU.[81] Another study in Brazil found a sepsis-related mortality rate of 43.8%.[14] On the other hand, the Brazilian population study that described the incidence of sepsis there[13] found a 34.7% mortality rate in septic patients, marginally better than that quoted prior to the initiation of the Saving Sepsis Campaign. Perhaps the most wide-reaching study is the PROGRESS International Sepsis Registry,[82] which tracked 12,881 patients with severe sepsis in 276 ICUs in 37 countries. Notably, mortality was 45% in the developing countries versus 30% in the developed countries, possibly due to the variety in management strategies employed in different countries. For example, while systemic antibiotics were given in 99% of all patients, fluid resuscitation and vasopressors were used in 94% of patients in Germany versus 62% of patients in India. Heterogeneity in patient population and severity of disease among the various countries make comparative conclusions difficult to draw from these studies. It seems apparent, though, that the mortality benefits seen in tightly controlled research protocols are not yet being seen worldwide, especially in developing countries.

The management strategy outlined earlier represents the preferred approach to the septic patient, based on evidence-based protocols and recommendations, though limited resources and lack of access to diagnostic tools may force reconsideration of the plan.[83,84] Diagnosis of sepsis may not be straightforward when access to invasive monitoring and laboratory facilities is limited. Medications may be in short supply or altogether unavailable. The ICU environment may also be unsuitable for caring for the septic patient, if one is even accessible. The key will be to identify the available measures that will have the most benefit to these particular patients (Table 132.6). In cases where vital interventions and diagnostic tools are not available, resources should be dedicated to bringing them to the area. Working in an organized and coordinated manner will help assure that each patient is getting the appropriate care.

Diagnostic tools are important in the evaluation of sepsis. Basic, necessary laboratory tests would include a complete blood count, basic biochemical tests, urinalysis and microbiologic culture capabilities. Additionally, depending on the regional importance of these tests, rapid HIV and malaria diagnostic tests may be necessary. Arterial blood gas measurement is useful in many cases, though each individual measure may be estimated from other tests, if needed. The measurement of serum lactate, an indicator of tissue perfusion is strongly suggested to guide management.

Systemic antibiotics are absolutely necessary in the treatment of the all stages of sepsis. The particular antibiotic regimen chosen will depend on the unique set of pathogens to which the patient is at risk. In many developing countries, this will include mycobacteria, viruses and protozoa, in addition to common bacteria. In the areas of the world with the high endemic rates of HIV infection, an expanded list must be considered. Parenteral antibiotics are generally preferred, especially in the more severe cases of sepsis, due to the high prevalence of bowel dysfunction and inconsistent GI absorption of medications. If parenteral antibiotics are not available, the enteral route may be used, provided the patient can swallow or enteral access is achieved. Regardless of the route, the antibiotics chosen must be appropriate and timely. Once the causative organism is identified, antibiotics may be narrowed.

Invasive hemodynamic monitoring may not be practical in some areas of the world. Arterial catheterization may not be realistic in many cases, nor is it always necessary. Similarly, central venous access may not always be required, especially if peripheral IV access can be obtained. The exception is in the case of vasopressor requirement, since most vasopressors are caustic if extravasated and require central venous access for administration. One reason to consider central venous access is for monitoring of $ScvO_2$, since blood pressure monitoring alone is insufficient for assessing tissue perfusion. Alternatively, serum lactate levels can be substituted, as a part of the chemistry testing discussed earlier.

Hemodynamic support is necessary in the many cases of sepsis, especially in progression to severe sepsis and septic shock. Isotonic IV fluids are the initial treatment

TABLE 132.6: Strategies for treatment of sepsis in developing countries

Intervention	*Goal treatments*	*Modifications (author recommendations only)*
Diagnosis	Clinical evaluation, laboratory data, assessment of organ systems, imaging, microbiologic confirmation	Clinical evaluation, basic laboratory data, other modalities where available
Antibiotics	Early administration of broad-spectrum parenteral antibiotics, taper based on microbiological results	Early administration of oral vs. parenteral antibiotics, possibly antimalarials or antimycobacterial meds, taper if micro is available
Hemodynamic monitoring	Invasive BP and CVP monitoring, $ScvO_2$ or lactate as goals	Clinical exam, other data as available if invasive monitoring not available
Fluid resuscitation	IV crystalloids or colloids, fluid challenge for low BP, additional fluids based on CVP and tissue perfusion parameters	IV (crystalloid vs. colloid) vs. oral rehydration, fluid challenge for low BP, additional fluids based on available clinical data
Hemodynamic support	Norepinephrine vs. dopamine (central venous catheter) for BP, dobutamine or RBC transfusion if needed for tissue perfusion	Dopamine (central venous catheter) for BP, RBC transfusions if Hct <30% and shock, dobutamine if available
Mechanical ventilation	ARDS ventilation (low tidal volumes) if indicated, directed by ABGs, weaning protocol	Oxygen, SpO2 monitoring, mechanical ventilation, ABGs if available and needed
Glucose control	Continuous IV insulin, goal blood sugar <180 mg/dL	Intermittent SQ insulin if able, blood sugar 180-200 or >200 depending on capabilities
Corticosteroids	Consider low dose IV hydrocortisone in vasopressor-unresponsive septic shock	Consider low dose IV hydrocortisone in vaso-vasopressor-unresponsive septic shock
Activated protein C	Consider rhAPC in septic shock with APACHE II >25 and no bleeding risk	Direct resources elsewhere if the hospital system or the patient cannot afford
Treatment protocols	Hospital-based protocols integrated with SSC Sepsis Resuscitation and Sepsis Management bundles	Hospital-based protocols integrated with SSC Sepsis Resuscitation and Sepsis Management bundles

of choice for sepsis-induced hypotension. Albumin is more widely used in Australia and Asia, possibly owing to better availability and/or lower cost.[82] Albumin is also more portable than saline, making it more attractive for use in remote regions. Limited resources may restrict the availability of IV fluids of any kind. In that case, those with mild disease and tolerating oral fluids may undergo a trial of oral fluid resuscitation. Vasopressors are often required to maintain adequate blood pressure and tissue perfusion. Dopamine and norepinephrine are considered equivalent in septic shock, though norepinephrine must be protected from light and requires refrigeration, while dopamine does not. Dopamine is thought to be stable for a minimum of 48 hours at room temperature,[85] making it more suitable for emergency rooms or remote locations, though hot and humid environments may reduce its shelf-life. Dobutamine and red blood cell transfusions are both recommended in cases where initial fluid resuscitation and blood pressure support fail to provide adequate tissue perfusion. Dobutamine must also be stored unmixed or refrigerated, though is also useful in the episodes of non-septic cardiogenic shock. In areas where blood donation is safe and economical, transfusion of red blood cells (RBCs) should be considered in anemic patients (hematocrit <30%) in shock, even if parameters of tissue perfusion cannot be measured. These two interventions are a part of successful early sepsis resuscitation protocols, though the role of these individual treatments in the success of those protocols is unclear. The expected benefit must be weighed against the necessary investment required to institute these therapies.

Mechanical ventilation becomes necessary when sepsis or SIRS manifest as ALI or ARDS. A more thorough discussion of mechanical ventilation is presented elsewhere in this book. The principles remain the same when applied to sepsis in developing countries. The use of portable ventilators may allow fewer ventilators to be used over a wider area, maximizing the use of scarce resources.

Glucose control remains an important part of sepsis management, with a goal blood sugar of <180 mg/dL. Optimal control is often achieved by using IV insulin in a continuous infusion. This method is labor-intensive and not always necessary. In many cases, subcutaneous insulin or intermittent IV insulin doses can achieve the same goals. Glucose testing kits and insulin should be available and used anywhere septic patients are cared for. If these resources are unavailable, periodic blood sugar monitoring is recommended during laboratory evaluation, though tight glucose control is generally not practical using this method and higher goals (>200 mg/dL) are suggested to prevent hypoglycemia. Oral hypoglycemics are not appropriate in the acute management of a septic patient.

Low-dose systemic corticosteroids should be considered in patients with septic shock that is not responsive to vasopressor therapy. Activated protein C provides a mortality benefit to patients with septic shock at the highest risk of death only. Both therapies are only recommended for use as adjuncts to the standard treatments previously described, and limited resources should be dedicated to those standard treatments.

The development of standardized protocols may be the area of most benefit to developing countries. The cost to develop a protocol specific to a hospital is minimal, especially given the fact that the Surviving Sepsis Campaign guidelines and protocols were developed with the aim of improving survival worldwide. The protocols are basic enough that they can be adapted to any unique situation. For example, in South America, the Latin American Sepsis Institute was created to "share sepsis information with scientific and lay communities in Latin America",[86] highlighting the difficulty in disseminating any information, even well-validated protocols, worldwide. Effective communication and well-defined roles are crucial in implementing the SSC guidelines as intended. The initial sepsis resuscitation bundle is meant to be completed within six hours, requiring rapid diagnosis and effective triage and management decisions in the emergency room or outpatient settings. Rapid access to diagnostic laboratory and imaging services is necessary to complete this goal. After the initial six hour resuscitation bundle, the sepsis management bundle is dominated by hospital-specific protocols. These protocols can easily be generated based on current literature and available resources.

Nonpulmonary Critical Care

Adebayo Esan, Lavanya Irugulapati, Liziamma George

INTRODUCTION

Patients are admitted to critical care units with several disease processes other than respiratory failure. In addition, patients admitted with respiratory failure often develop further organ dysfunctions that require aggressive management. In this chapter, we will discuss some of the common nonpulmonary critical care diagnoses and their corresponding management.

GASTROINTESTINAL DISEASE IN CRITICAL CARE

Gastrointestinal Bleeding

Gastrointestinal (GI) bleeding is a medical emergency necessitating admission to the critical care unit. It is common in males and elderly patients.[1] Upper GI bleed is defined as bleeding above the level of the ligament of Treitz while lower GI bleed is bleeding below the level of the ligament of Treitz.[2] Upper GI bleed tends to occur more commonly than its lower GI counterpart and has a mortality that ranges from 6 to 12% as opposed to 5% in lower GI bleed.[3,4] Recurrent acute or chronic bleed from the digestive tract without an obvious etiology after a normal esophagogastroduodenoscopy (EGD) and colonoscopy is known as obscure GI bleed.[5] The most common causes of upper and lower GI bleeding are listed in Tables 133.1 and 133.2 respectively.

TABLE 133.1: The common causes of upper gastro-intestinal bleeding.

- Peptic ulcer disease - MCC worldwide (duodenal ulcers, gastric ulcers, stomal ulcers)
- Erosive gastritis, esophagitis and duodenitis (alcohol, aspirin, NSAIDs)
- Esophageal and gastric varices (caused by portal hypertension)
- Mallory-Weiss syndrome
- Stress ulcers
- AVM
- Malignancy
- Aortoenteric fistula

Abbreviations: GI: Gastrointestinal, MCC: Most common cause, NSAIDs: Non-steroidal anti-inflammatory drugs, AVM: Arteriovenous malformation.

TABLE 133.2: The common causes of lower gastro-intestinal bleeding

- Diverticulosis
- Hemorrhoids
- AVM/Angiodysplasia/Aortoenteric fistula
- Neoplasia
- Polyps
- Benign anorectal disease (fissures, ulcers)
- Upper GI source
- Small bowel source

Abbreviations: GI: Gastrointestinal, AVM: Arteriovenous malformation.

Upper Gastrointestinal Bleeding

Clinical features: Clinical manifestations depend on the rate and amount of bleeding. These patients should be promptly assessed for hemodynamic status, which involves measuring the pulse rate, blood pressure, urine output and postural hemodynamic changes. Pulse rate of ≥100 beats per minute, systolic blood pressure <100 mm Hg, postural changes, i.e. an increase in the pulse of ≥20 beats per minute or a drop in systolic blood pressure of ≥20 mm Hg on standing are significant. Airway protection is needed for patients with altered mental status or massive hematemesis. History of alcohol abuse, Non-steroidal Anti-inflammatory Drug (NSAID) usage, liver disease and family history of gastrointestinal or other malignancies, recent retching, prior surgery and other medication usage may point to the etiology of GI bleeding. Elderly patients, who potentially have an age-related compromised cardiac reserve, may present with symptoms of chest pain and shortness of breath rather than GI bleed, suggestive of myocardial ischemia. Other symptoms such as fatigue and dyspnea tend to occur with chronic blood loss. Signs specific for upper GI bleeding include hematemesis, bloody gastric lavage, melena and hematochezia. Bleeding through the rectum is usually indicative of lower GI bleeding; however, massive upper GI bleeding can cause fresh blood to pass through the rectum.[6] Because of the possible contributing factors and associated complications, patients should also be examined for signs of liver and cardiac disease.

Diagnosis: The initial step performed in patients with suspected upper GI bleed is to place a nasogastric tube, so as to aspirate gastric contents. While a coffee-ground aspirate or fresh blood is diagnostic of upper GI bleed, its absence will not rule out upper GI bleed in up to 20% of patients.[7] The presence of blood in the stomach is an indication for an urgent EGD for either diagnostic and/or therapeutic purposes. The use of cold or iced saline lavages in these patients has not been shown to improve outcome.[8] However, diagnostic evaluation should only be undertaken after initial stabilization of the patient has taken place.

In order to assess the severity of GI bleeding as well as to evaluate for any contributing etiological factors, the following laboratory tests should be performed: a complete blood count, electrolytes, urea and creatinine, liver function tests and coagulation profile. Blood samples should also be sent for typing and cross-matching. It is important to note that the hematocrit may be normal in recent massive GI bleed and can, therefore result in an underestimation of the severity.

Management: Irrespective of the bleeding site, the management of acute GI bleeding should include hemodynamic stabilization, localization of the bleeding site and specific therapeutic interventions.[9,10] Supplemental oxygen should be provided to ensure adequate tissue oxygenation and all patients should also be placed on cardiac monitors.

Intravascular volume repletion with crystalloid infusion through two large bore (16 or 18 gauge) intravenous lines should begin immediately. Patients with unstable vital signs even after initial stabilization should be transfused with packed red cells. A guide for hemodynamic assessment and transfusion requirement is shown in Table 133.3.[11]

In cases with exsanguinating blood loss, attempts at localization and control of bleeding through endoscopic or surgical procedures should be done simultaneously. The threshold for transfusion must be individualized as the majority of patients do not require transfusion unless the hemoglobin (Hb) level is less than 7 g/dl.[12]

The Blatchford and Rockall scoring systems are used for risk stratification of upper GI bleeding (Tables 133.4

TABLE 133.3: The signs, symptoms and fluid replacement strategies in patients with hypovolemic (hemorrhagic) shock

Clinical evaluation and initial management of hypovolemic shock				
Blood loss (mL)	<750	750 to 1500	1500 to 2000	>2000
Blood loss (%bv)	<15%	15 to 30%	30 to 40%	>40%
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mmHg)	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14 to 20	20 to 30	30 to 40	>35
Urine output (mL/hr)	>30	20 to 30	5 to 15	Insignificant
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

Abbreviation: BV: Blood volume
Adapted from Grenvick A et al.[11]

TABLE 133.4: The Blatchford bleeding score which predicts the need for treatment in patients with upper gastrointestinal bleeding. A higher score (≥ 6) is associated with an increased risk of re-bleeding while a lower score (< 6) is associated with a decreased re-bleeding risk

At presentation	*Points*
• Systolic blood pressure (mm Hg)	
100 to 109	1
90 to 99	2
< 90	3
• Blood urea nitrogen	
6.5 to 7.9 mmol/L	2
8.0 to 9.9 mmol/L	3
10 to 24.9 mmol/L	4
≥25 mmol/L	6
• Hemoglobin for men	
12.0 to 12.9 g/dL	1
10.0 to 11.9 g/dL	3
<10.0 g/dL	6
• Hemoglobin for women	
10.0 to 11.9 g/dL	1
<10.0 g/dL	6
• Other variables at presentation	
Pulse ≥ 100	1
Melena	1
Syncope	2
Hepatic disease	2
Cardiac failure	2

Adapted from Blatchford O et al.[13]

and 133.5).[13,14] Higher scores are indicative of rebleeding and death while lower scores identify patients who do not need urgent intervention.[15] Localization of bleeding site is the cornerstone of the management of upper GI bleeding. Endoscopy should be performed within 24 hours of patient presentation. The administration of promotility agents are not routinely recommended before endoscopy. Furthermore, the risk of rebleeding based on endoscopic findings can be assessed using Forrest classification (Table 133.6).[16,17] Patients with grades 2C and 3 are considered low risk for rebleeding, while patients with high-risk lesions should undergo endoscopic hemostasis to prevent recurrent bleeding.[16] A second-look endoscopy is not routinely recommended. In addition, in patients with coagulation abnormalities, endoscopy should not be delayed and the risk/benefit ratio should be assessed carefully.

Medical therapy should be used as an adjunct to endoscopic therapy. Pre-endoscopic administration of proton pump inhibitors (PPIs) decreases the need for endoscopic intervention.[18] Administration of a PPI has also been shown to decrease rebleeding, surgical intervention and mortality.[19,20] In addition, it is reported that in patients with recurrent bleeding, repeated endoscopy is preferred to surgical intervention.[21]

Angiography and embolization is recommended for patients in whom acute bleeding is not controlled

TABLE 133.5: The Rockall scoring system which is used to identify patients at risk for developing unfavorable outcomes following acute upper gastrointestinal bleeding. A complete Rockall score of ≤ 2, i.e. following endoscopy is associated with a good prognosis, i.e. low risk for re-bleeding and death[14]

Variable	*Points*		
• **Age**			
< 60 yrs	0	Clinical Rockall score (0 to 7)	Complete Rockall score (0 to 11)
60 to 79 yrs	1		
> 80 yrs	2		
• **Hemodynamic status**			
Shock absent: SBP > 100 mm Hg and HR < 100 beats/min	0		
Shock absent: SBP > 100 mm Hg and HR > 100 beats/min	1		
Shock present: SBP < 100 mm Hg and HR > 100 beats/min	2		
• **Co-existing illness**			
Ischemic heart disease, congestive heart failure and other major illness.	2		
Renal failure, hepatic failure, metastatic cancer	3		
• **Endoscopic diagnosis**			
No lesion observed, Mallory-Weiss tear	0		
Peptic ulcer, erosive disease, esophagitis	1		
Cancer of upper GI tract	2		
• **Endoscopic stigmata of recent hemorrhage**			
• Clean based ulcer, flat pigmented spot	0		
• Blood in upper GI tract, active bleeding, visible vessel, clot	2		

Abbreviations: SBP: Systolic blood pressure, HR: Heart rate.

TABLE 133.6: The endoscopic appearance and associated re-bleeding risk in patients with upper gastrointestinal bleeding

Class	*Appearance*	*Risk of Re-bleeding*
1A	Spurting blood	Very high → early surgical intervention
1B	Oozing blood	Very high
2A	Non-bleeding visible vessel	High
2B	Adhering clot	High
2C	Flat lesions and pigmented spot	Low
3	Clean base ulcer	Low

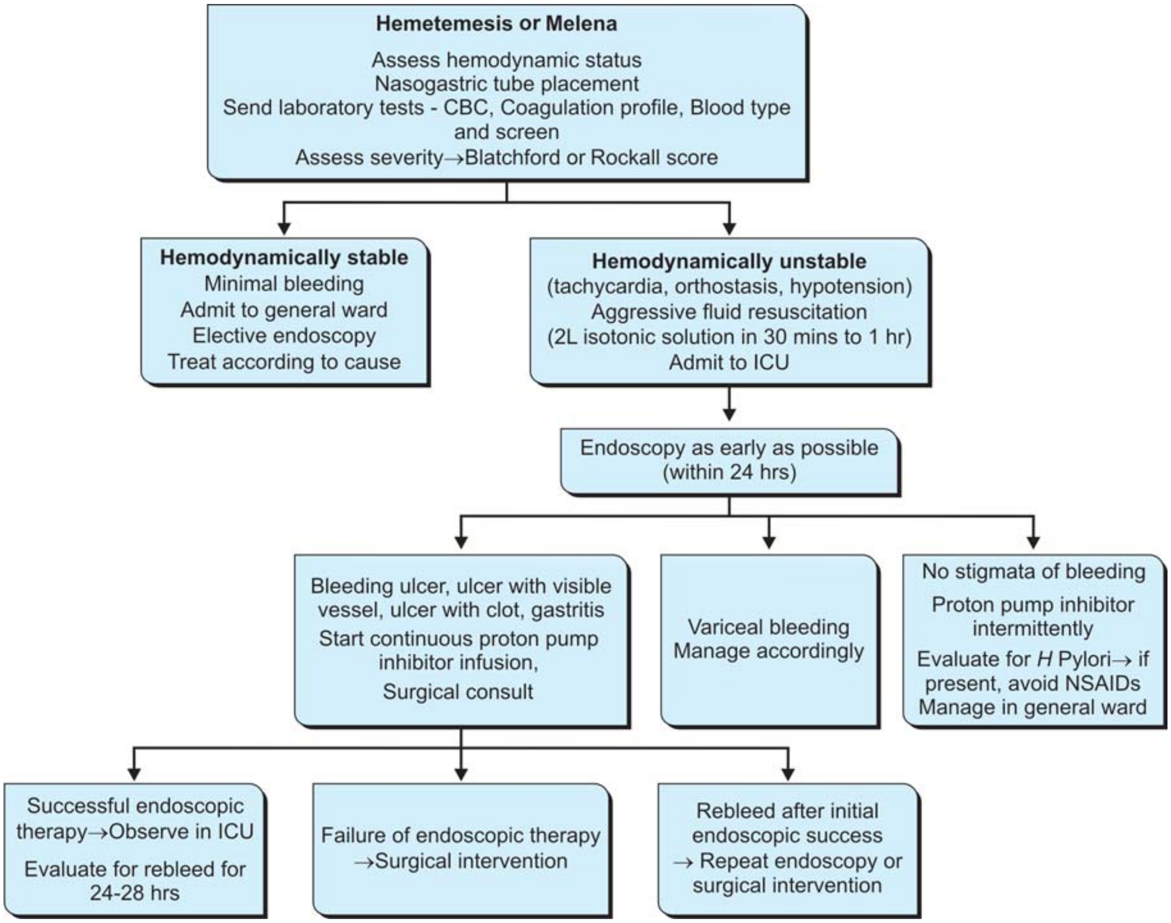
by endoscopic treatment. Successful angiographic identification of the bleeding site requires a bleeding rate of 0.5 to 1 ml per minute.[22] The complications of this procedure include bowel ischemia, infarction and contrast-induced renal failure.

The surgical team should be involved early in the management of these patients so as to augment prompt response when all else has failed in ensuring hemostasis.

Recapitulation: Patients with upper GI bleeding require a multidisciplinary approach; initial stabilization improves outcome for these patients; patients should be risk stratified for management in the critical care unit; early endoscopy (within 24 hours) is the cornerstone for management; medical therapy using PPIs is an adjunct to endoscopic therapy. An algorithm for the management of upper GI bleeding is shown in Figure 133.1.[23]

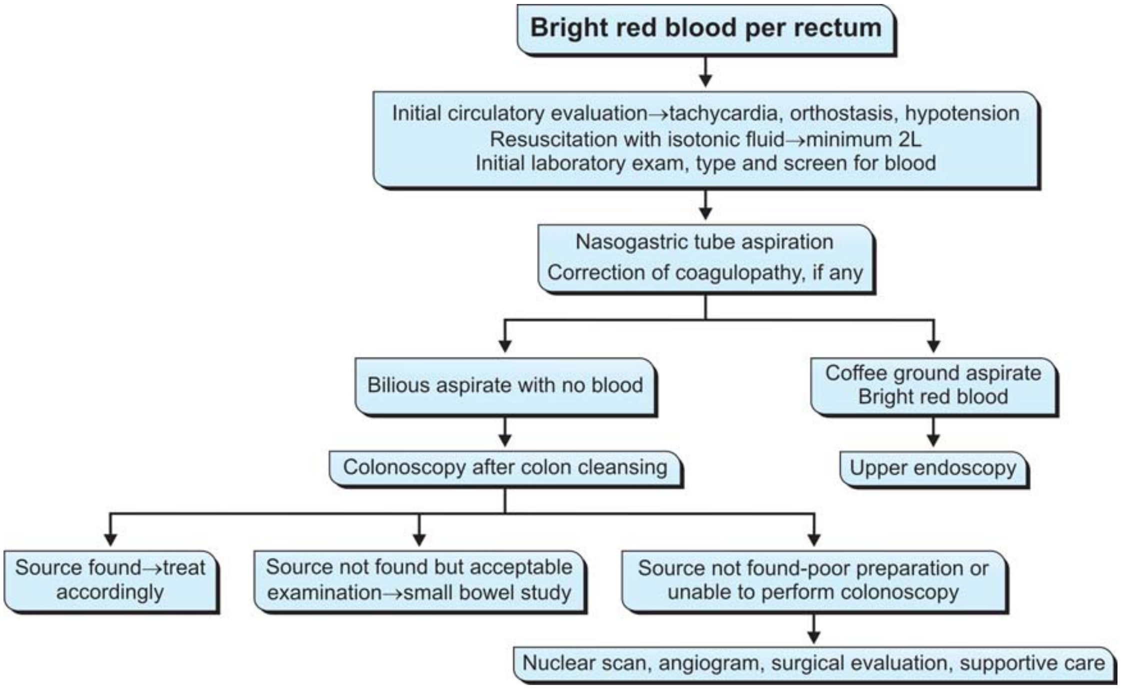
Lower Gastrointestinal Bleeding

Clinical features: Lower GI bleeding is defined as bleeding distal to the ligament of Treitz. These patients tend to present with hematochezia or maroon colored stools. The common etiologies contributing to the development of lower GI bleeding are shown in Table 133.2.



Hemetemesis or Melena
Assess hemodynamic status
Nasogastric tube placement
Send laboratory tests - CBC, Coagulation profile, Blood type and screen
Assess severity→Blatchford or Rockall score
Hemodynamically stable
Minimal bleeding
Admit to general ward
Elective endoscopy
Treat according to cause
Hemodynamically unstable
(tachycardia, orthostasis, hypotension)
Aggressive fluid resuscitation
(2L isotonic solution in 30 mins to 1 hr)
Admit to ICU
Endoscopy as early as possible (within 24 hrs)
Bleeding ulcer, ulcer with visible vessel, ulcer with clot, gastritis
Start continuous proton pump inhibitor infusion,
Surgical consult
Variceal bleeding
Manage accordingly
No stigmata of bleeding
Proton pump inhibitor intermittently
Evaluate for H Pylori→ if present, avoid NSAIDs
Manage in general ward
Successful endoscopic therapy→Observe in ICU
Evaluate for rebleed for 24-28 hrs
Failure of endoscopic therapy →Surgical intervention
Rebleed after initial endoscopic success → Repeat endoscopy or surgical intervention

Fig. 133.1: The management of upper gastrointestinal bleeding, which is focused around hemodynamic stabilization and localization of the bleeding site.
Abbreviations: CBC: Complete Blood Count, ICU: Intensive Care Unit, *H pylori: Helicobacter pylori,* NSAID: Non-Steroidal Anti-inflammatory Drug.



Bright red blood per rectum
Initial circulatory evaluation→tachycardia, orthostasis, hypotension
Resuscitation with isotonic fluid→minimum 2L
Initial laboratory exam, type and screen for blood
Nasogastric tube aspiration
Correction of coagulopathy, if any
Bilious aspirate with no blood
Coffee ground aspirate
Bright red blood
Colonoscopy after colon cleansing
Upper endoscopy
Source found→treat accordingly
Source not found but acceptable examination→small bowel study
Source not found-poor preparation or unable to perform colonoscopy
Nuclear scan, angiogram, surgical evaluation, supportive care

Fig. 133.2: An algorithmic approach to the management of lower gastrointestinal bleeding

Diagnosis: The initial stabilization of lower GI bleeding is not different from that of upper GI bleeding. The localization of bleeding is done by colonoscopy which identifies the bleeding in 60 to 80% of cases. The other options are nuclear scanning using technetium-99m-labeled red blood cell (Tc-99 m RBC) scan and arteriography. Radionuclide scanning is a more sensitive but less specific modality (may not localize the lesion and no therapeutic intervention can be done) and requires at least 0.1 to 0.5 ml of bleeding per minute. Barium studies have no role in the evaluation of lower GI bleed. A multi-detector Computed Tomography (CT) scan has been used to localize massive GI bleeding in some reports.[24] Arteriography of both superior and inferior mesenteric arteries can be used to identify the source of bleeding. Some studies recommend radionuclide scanning before angiography, so as to decrease the incidence of negative tests.

Management: An algorithm for the management of lower GI bleeding is demonstrated in Figure 133.2.[25]

Acute Variceal Hemorrhage

Acute variceal hemorrhage is one of the complications of portal hypertension requiring critical care unit admission. Patients with Child Pugh classification of B or C (Table 133.7) have a higher incidence of variceal bleeding and are associated with a mortality of 15 to 20%.[26] Patients often present with massive upper GI bleeding associated with hemodynamic instability.

The specific treatment strategies include the use of medications, endoscopy, surgical interventions, transjugular intrahepatic shunt, balloon tamponade and the prevention of recurrent bleeding. After initial stabilization of the patient, medications directed towards splanchnic vasoconstriction should be utilized to decrease portal pressure. The commonly used agents are vasopressin, telipressin, somatostatin and its analogues. Vasopressin causes direct vasoconstriction of splanchnic arterioles leading to decreased portal pressure. The major side effects include systemic vasoconstriction, particularly coronary vessels. The use of nitrates in addition to vasopressin is recommended to decrease these side effects with added therapeutic benefit.[27] Notably, vasopressin has minimal effects on rebleeding. Telipressin, a vasopressin analogue can be used as an alternative to vasopressin, which has less side effects than vasopressin. Somatostatin, an indirect vasoconstrictor of splanchnic circulation, rapidly decreases the portal pressure with minimal side effects. It is superior to vasopressin in patients with variceal hemorrhage.[28] The infusion is continued for 2 to 5 days and has no significant effect on mortality.

TABLE 133.7: The modified Child-Pugh classification of the severity of liver disease with the associated risk of mortality[26]

Parameters	*Points Assigned*		
	1	2	3
Ascites	Absent	Slight	Moderate

Endoscopic banding or sclerotherapy is the definitive treatment for acute variceal bleeding.[29] Both telipressin and somatostatin analogues are as effective as endoscopic therapies, however, combination of both medical and endoscopic therapies are more beneficial to control bleeding.[30-32] Endoscopic therapies are associated with complications such as ulceration, mediastinitis, esophageal perforation as well as sepsis. Balloon tamponade is considered when medical and endoscopic approaches fail to achieve hemostasis or when there is a lack of expertise to perform endoscopic interventions. This is a temporary measure until definitive treatment can be undertaken. The common tubes used are the Sengstaken- Blakemore tube or the Minnesota tube. These tubes have gastric and esophageal bulbs to tamponade the varices and are effective in 30 to 90% of patients. The complications associated with their use include esophageal rupture and rebleeding.[33]

Trans-jugular portohepatic shunt can also be used as a temporary measure to decrease the portal venous pressure by creating a shunt between the hepatic and portal veins. In addition to controlling bleeding, prophylactic short-term antibiotics are recommended to prevent spontaneous bacterial peritonitis. Ceftriaxone or fluoroquinolones for 7 days are used in most of the studies.[34] Rebleeding is a significant problem and the risk factors are:

- Age > 60 years
- Child class C patients
- Large varices
- Renal failure
- Significant initial bleed (presence of hemodynamic instability)
- Hgb < 8 g/dL
- Hepatic venous pressure gradient > 20 mm Hg

Correction of coagulopathy and thrombocytopenia (platelets < 50 x 10^9/L) is vital in these patients, with careful attention to volume overload. There are few reports of using recombinant factor VIIa in severely fluid overloaded patients.

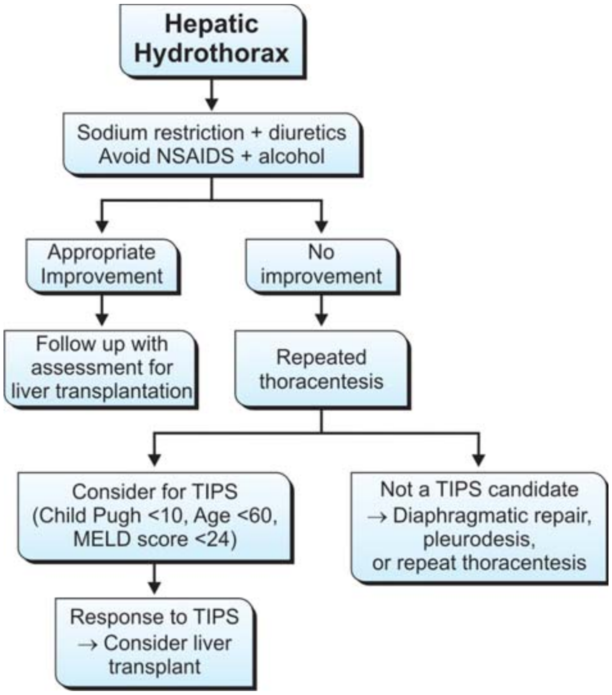
Other disorders associated with liver disease necessitating intensive care unit admission include lung disorders associated with liver failure. The major conditions are hepatopulmonary syndrome, hepatic hydrothorax and portopulmonary hypertension.

The hepatopulmonary syndrome (HPS) is a pulmonary vascular disorder characterized by pulmonary vascular dilatation, intrapulmonary arterio-venous shunting leading to ventilation-perfusion mismatch in the setting of liver disease. It has no association with the severity of liver disease.[35] Patients usually present with shortness of breath associated with platypnea and orthodeoxia (dyspnea and desaturation when position changes to sitting from recumbent position). The chest X-ray is usually normal or may show increased vascular markings, while the arterial blood gas (ABG) shows hypoxemia PaO_2 < 80 mm Hg with increased alveolar-arterial gradient (> 15 mm Hg).

Contrast echo-cardiography (microbubbles in left atrium within 3 to 6 cardiac cycles) or perfusion lung scanning using technetium labeled macroaggregates of albumin (presence of isotope in brain and kidney) are the preferred diagnostic tests. Liver transplantation is the treatment of choice.[36]

Portopulmonary hypertension occurs in patient with portal hypertension and is managed similar to Class 1 pulmonary hypertension.

Hepatic hydrothorax presents as massive pleural effusion mostly involving the right hemithorax. Its management is depicted in Figure 133.3.[37] The first step in management is therapy with low sodium diet (70 to 90 mEq/day) and diuretics. If there is no response to diuretics, therapeutic thoracentesis of approximately 2 liters can be attempted followed by diuretics at lower doses if possible. If patients do not respond to diuretics or develop complications, they should be considered for a transjugular intrahepatic portosystemic shunt (TIPS) placement. This measure may help as a bridge to liver transplantation. TIPS placement is best considered in patients younger than 60 years of age, without hepatic encephalopathy and/or those with child class A or B cirrhosis. For patients that cannot undergo TIPS placement, pleurodesis or diaphragmatic repair by thoracoscopy should be considered. Chest tube placement should be avoided as it is associated with severe complications.[38, 39]



Hepatic Hydrothorax
Sodium restriction + diuretics Avoid NSAIDS + alcohol
Appropriate Improvement
No improvement
Follow up with assessment for liver transplantation
Repeated thoracentesis
Consider for TIPS (Child Pugh <10, Age <60, MELD score <24)
Not a TIPS candidate → Diaphragmatic repair, pleurodesis, or repeat thoracentesis
Response to TIPS → Consider liver transplant

Fig. 133.3: An algorithm outlining management of patients presenting with hepatic hydrothorax.

Acute Liver Failure

Acute liver failure is defined as the onset of hepatic encephalopathy and coagulopathy within 26 weeks of jaundice in a patient with pre-existing liver disease.[40] Patients should be managed in a critical care unit at the onset of encephalopathy.

The treatment of liver failure according to the specific etiology is outlined in Table 133.8.[41]

Management of Complications

Hepatic encephalopathy is a reversible neurological dysfunction, occurring in patients with liver failure. Neurotoxins like ammonia, oxidative stress, production of false neurotransmitters and alteration in the blood brain barrier are implicated for its development. In addition to correction of precipitating factors, ammonia production in the gut is reduced with the use of lactulose and nonabsorbable antibiotics such as neomycin and rifaximin.[42] Infections contribute significantly to the mortality of these patients and should be treated aggressively.

Psychomotor agitation seen in patients with hepatic encephalopathy may be worsened by benzodiazepines and propofol through gamma amino butyric acid pathways. Flumazenil, a benzodiazepine antagonist, is reported to have short term benefit in patients with hepatic encephalopathy. For analgesia, fentanyl is used in these patients.[43] Even though these patients are coagulopathic, active bleeding is rare. The occurrence of upper GI bleeding is prevented by the use of either H2 blockers or PPIs.[44] Parental vitamin K is recommended for all patients with acute liver failure, however, routine fresh frozen plasma (FFP) administration is not recommended and cryoprecipitate is given when fibrinogen levels are less than 100 mg/dL. Recombinant factor VIIa is recommended if there is volume overload and fresh frozen plasma fails to correct coagulopathy or before invasive procedures with high risk of bleeding.[45] Further studies are needed to define the exact role of this agent. Nevertheless, factor VIIa should not be given to patients with acute myocardial infarction, stroke or other thromboembolic disorders.

Nutritional supplementation through the enteral route is preferred to parenteral nutrition in these patients.[46] However, patients with hypoglycemia should get intravenous glucose infusion.

TABLE 133.8: The etiology, treatment and transplant criteria for acute liver failure[41,51]

Etiology	*Treatment*	*Criteria for transplant*
	NAC oral: 140 mg load then 70 mg/kg every 4 hours	Arterial pH 7.3 or all of following: 1. PT > 100 sec (INR > 6.5) 2. Cr > 3.4 mg/dl 3. Grade 3 or 4 encephalopathy
	NAC IV: 150 mg/kg load then 12.5 mg/kg hourly X 4 hrs then 6.25 mg/kg hourly	Meld > 33, APACHE > 15
Amanita (mushroom)	Penicillin G: 1g/kg daily IV and NAC as above	PT > 100 sec (INR > 6.5) or any three of the following: 1. NANB/drug/halothane etiology 2. Jaundice to encephalopathy > 7 days 3. Age < 10 or > 40 yrs 4. PT > 50 sec (INR > 3.5) 5. Bilirubin > 17.4 mg/dl 6. Hepatocyte necrosis > 70%
HSV	Acyclovir 30 mg/kg daily IV	
AIH	Methylprednisolone 60 mg/day IV	
HBV	Lamivudine 100 to 150 mg/daily orally	
AFLP/HELLP	Delivery of fetus	

Abbreviations: NAC: N-acetylcysteine, PT: Prothrombin time, INR: International normalized ratio, Cr: Creatinine, MELD: Model for end-stage liver disease, APACHE: Acute physiology and chronic health evaluation, IV: Intravenous, NANB: Non-A, Non-B Hepatitis, HSV: Herpes Simplex Virus, AIH: Autoimmune Hepatitis, HBV: Hepatitis B Virus, AFLP: Acute Fatty Liver of Pregnancy, HELLP: Hemolysis, Elevated Liver Enzymes, Low Platelets

Nonconvulsive seizures can also occur in these patients, however, routine seizure prophylaxis is not recommended. Electroencephalography monitoring is suggested for patients with grade III or IV encephalopathy, sudden deterioration of mental status or myoclonus.

Acute liver failure patients, who develop hypotension, should be treated aggressively, initially with fluids to correct volume status and subsequently with vasopressors if fluid administration alone does not correct the hypotension.

Cerebral edema and raised intracranial pressure increases the morbidity and mortality for these patients. Computerized tomography of the brain is recommended for patients with an advanced hepatic encephalopathy.[47] Placement of an intracranial pressure monitoring device for these patients is controversial at this time but should be considered for liver transplant candidates.[48] The management of patient with intracranial hypertension includes keeping the head of bed at 30° in the neutral position and the maintenance of euthermia; however, prophylactic hyperventilation is not recommended.[49] Conversely, acute hyperventilation can be given to patients with brain herniation. In addition, specific therapies such as mannitol are utilized when intracranial pressure (ICP) is > 25 mm Hg for > 10 minutes. The dose ranges from 0.25 to 1.0 g/kg over 30 minutes.[50] The dose can be repeated if serum osmolality is < 320 mOsm/L or ICP > 25 mm of Hg. Other treatment modalities include hypertonic saline, induction of moderate hypothermia, barbiturate coma and indomethacin infusion. Patients with acute liver failure are candidates for orthotopic liver transplantation. The criteria for transplantation are shown in Table 133.8.[51, 52]

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an infection of ascitic fluid in the absence of an intra-abdominal source of infection.[53-56] It is a common and life-threatening complication of cirrhosis. SBP occurrence is rare in non-cirrhotic patients as opposed to cirrhotic ones. Bacterial translocation into ascitic fluid is commonly believed to be a causative factor for the development of SBP, however, current research shows that SBP is the result of the interplay of several factors such as prolonged bacteremia resulting from defective local and humoral immunity, intrahepatic shunting of blood, defective bactericidal action of ascitic fluid and transabdominal introduction of infection.[57] The microorganisms responsible for SBP are isolated in 60 to 70% of cases and colonic bacteria are cultured in 65% of cases with *Escherichia coli* and *Klebsiella* species being the common organisms isolated.

Clinical Features

SBP should be suspected in all cirrhotic patients with ascites, as the clinical manifestations can be very subtle as well as non-specific, with a broad range of clinical expression. Ascitic fluid analysis should be performed in all patients with ascites who are admitted to hospital, in addition to those presenting with abdominal pain, fever and encephalopathy.

Diagnosis and Management

SBP is identified when an ascitic fluid analysis demonstrates a polymorphonuclear cell count greater than 250 cells/mm^3. A positive culture of ascitic fluid is noted in only 30% of cases and is usually not required for diagnosis. Antibiotics, preferably a third generation cephalosporin, should be started immediately after a positive ascitic fluid tap.[58] Renal dysfunction can also occur in patients with SBP as a consequence of large-volume paracentesis. Intravenous albumin administration has been shown to reduce the risk of renal impairment taking place.[59] However, albumin has been proposed to be used in patients with serum creatinine > 1 mg/dl, blood urea nitrogen > 30 mg/dL and total bilirubin > 4 mg/dL.[60] Following a single episode of SBP, patients should receive long-term prophylaxis with either norfloxacin or trimethoprim/sulphamethoxazole.

Severe Acute Pancreatitis

Acute pancreatitis is an inflammatory condition of the pancreas resulting in abdominal pain and elevation of the serum levels of the pancreatic enzymes. It is a self-limited disease in most cases. About 20% of patients develop acute necrotizing pancreatitis, leading to multiorgan failure and death. The common etiologies include gallstones, alcohol consumption, hypertriglyceridemia, smoking, hypercalcemia, drugs, trauma, pancreatic divisum and infections.

Clinical Features

Pancreatic enzymes are activated within the acini causing damage to the pancreatic tissues and vasculature. In necrotizing pancreatitis the inflammation extends into the adjacent tissues. Patients present to the ICU with fever, tachycardia, shock and multiorgan dysfunction.

Diagnosis

A CT scan of the abdomen and Magnetic Resonance Pancreaticoduodenography (MRCP) are the best radiological tests for the diagnosis and staging of acute pancreatitis, though the MRCP gives a better image of the pancreatic and biliary duct system.[61-63] A number of scoring systems have been developed to assess the severity of pancreatitis. The most well-known scoring system is Ranson's criteria (Table 133.9).[64] Other scoring systems include APACHE II scores (> 8 is considered significant) and CT scan grading.

Management

A contrast enhanced abdominal CT-scan should be performed for patients with acute pancreatitis within

TABLE 133.9: Ranson's criteria for predicting the severity of acute pancreatitis. Each parameter is assigned a score of 1 if present. A higher score is associated with higher mortality (score: < 3 → < 3% mortality; 3-6 → 15% mortality; > 6 → 40% mortality)[64]

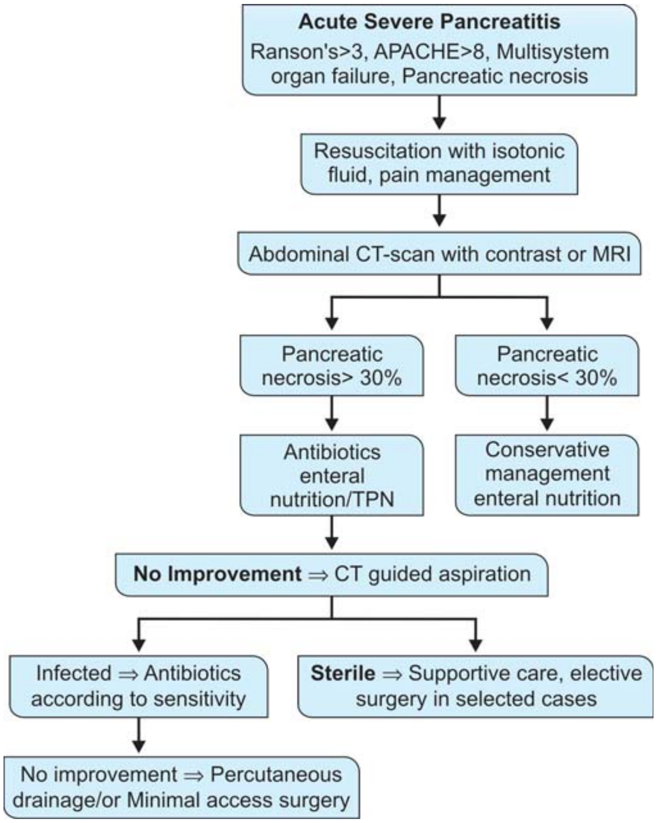
0 hours	
Age	> 55
White blood cell count	> 16,000/mm^3
Blood glucose	> 200 mg/dL (11.1 mmol/L)
Lactate dehydrogenase (LDH)	> 350 U/L
Aspartate aminotransferase (AST)	> 250 U/L
48 hours	
Hematocrit	Fall by ≥ 10%
Blood urea nitrogen	Increase by ≥ 5 mg/dL (1.8 mmol/L) despite fluids
Serum calcium	< 8 mg/dL (2 mmol/L)
Partial pressure of oxygen (pO_2)	< 60 mm Hg
Base deficit	> 4 mEq/L
Fluid sequestration	> 6000 ml

72 hours of admission to the ICU. Fluid resuscitation at a rate of 200 to 300 cc per hour of isotonic solution is required to prevent acute renal tubular necrosis. Hematocrit measurement can guide the adequacy of fluid resuscitation. Pain is managed with meperidine, morphine or fentanyl. Infections caused by enteric gram negative organisms increase the morbidity and mortality of these patients. The role of prophylactic antibiotics is controversial: the use of carbapenems as prophylactic agents for 2 weeks in patients with necrotizing pancreatitis is reported.[65] Anti-fungal agents are not given routinely for these patients. CT-guided aspiration and drainage of collections are performed in patients who do not improve with at least 1 week of antibiotics. Open necrosectomy is not favored.[66-68] Early enteral feeding via a nasojejunostomy tube is associated with decreased infectious complications and early recovery compared to parenteral nutrition.[69] In patients with gallstone pancreatitis, the need for an early Endoscopic Retrograde Cholangiopancreatography (ERCP) is dictated by the presence of acute cholangitis and jaundice. If the liver enzymes remain elevated or increasing, early ERCP is recommended. An algorithm for the management of acute pancreatitis is shown in Figure 133.4.

HEMATOLOGY IN CRITICAL CARE

Anemia

Anemia, acute or chronic is a frequent problem in critically ill patients admitted into Intensive Care Units (ICUs)[70,71] and can result from a number of causes (Table 133.10).[72] The proinflammtory state seen in critically ill patients result in a blunted erythropoietic response to anemia in addition to abnormalities in iron metabolism, further complicating the clinical course.[73-77] It has been reported that 63 and 29% of critically ill patients admitted into the ICU have an admitting Hgb concen-tration of less than 12.0 g/dL and 10.0 g/dL respectively with Hgb concentrations on average decreasing by approximately 0.5 g/dL/day in nonseptic patients (without active bleeding or hemolysis) during the first 3 days of ICU stay.[76,78,79] The Hgb concentration remains stable thereafter in these patients.[79] Conversely, in septic patients, Hgb concentrations on an average decrease by 0.8 g/dL/day during the first 3 days in the ICU and subsequently by 0.3 g/dL/day.[79] Historically, the lower limits of normal Hgb concentration in adults have been suggested to range from 12.7 to 13.7 g/dL in men and



Acute Severe Pancreatitis
Ranson's>3, APACHE>8, Multisystem organ failure, Pancreatic necrosis
Resuscitation with isotonic fluid, pain management
Abdominal CT-scan with contrast or MRI
Pancreatic necrosis> 30%
Pancreatic necrosis< 30%
Antibiotics enteral nutrition/TPN
Conservative management enteral nutrition
No Improvement ⇒ CT guided aspiration
Infected ⇒ Antibiotics according to sensitivity
Sterile ⇒ Supportive care, elective surgery in selected cases
No improvement ⇒ Percutaneous drainage/or Minimal access surgery

TABLE 133.10: The different etiologies of anemia in the intensive care unit[72]

Mechanism	*Etiology*
Blood loss	Phlebotomy Gastrointestinal bleeding Other sources of bleeding Surgery and other invasive procedures
Diminished erythropoiesis	Decreased erythropoietin synthesis Erythropoietin resistance Iron deficiency Nutritional deficiencies Myelo-suppressive drugs or toxins Bone marrow disorders Endocrine disorders
Pre-existing chronic anemia	Anemia of chronic disease
Increased erythrocyte destruction	Defective production of Hgb sub-units Hemolysis Autoimmune diseases Drugs
Hemodilution	Aggressive fluid resuscitation

Abbreviations: Hgb-Hemoglobin

11.5 to 12.2 g/dL in women. According to recent data, maintaining Hgb concentration of 7.0 to 9.0 g/dL has been considered to be sufficient and red cell transfusion is considered when Hgb concentration is less than 7.0 g/dL.[71,80,81,82] Clinicians must weigh the potential benefits against the possible risks and complications of red cell transfusions.

Clinical Features

The clinical consequences of anemia will depend on the degree of anemia, the rate at which it has developed, the oxygen demands of the patient which tends to be high in the critically ill, as well as the ability of the patient to compensate for these changes. High-risk groups in which anemia is considered to be less tolerated and more vulnerable to adverse outcomes include the elderly, critically ill patients and patients with respiratory, coronary or cerebrovascular disease.[70] The symptoms and signs are nonspecific.

Diagnosis

Detailed clinical history and physical examination supplemented with laboratory evaluations will give some clues towards the etiology of anemia.[72,83] Laboratory tests include a complete blood count (CBC) including red blood cell indices and white blood cell differentials.[83] It is important to compare these results with prior CBCs so as to determine the onset of the anemia, as well as to identify trends and progression of disease. Other laboratory tests that can be performed as indicated to determine the etiology of anemia includes peripheral blood smear; iron profile studies, folate levels and vitamin B_{12} levels to evaluate nutritional deficiencies; bilirubin level, Lactate Dehydrogenase (LDH) levels, haptoglobin levels and Coomb's test to evaluate degree and type of hemolysis; hemoglobin electrophoresis; thyroid function tests; blood urea nitrogen and creatinine levels; and bone marrow examinations.[83, 84]

Management

Anemia of acute onset such as in gastrointestinal bleeding, is typically treated with the administration of physiologic crystalloids, colloidal fluids or red cell transfusions.[72] However, in patients with a more chronic evolution of anemia, treatment will depend on the underlying etiology.[72] Iatrogenic causes such as phlebotomy are common in the ICU and range from 40 to 70 mL/day.[71,76,79] Blood conservation techniques such as use of small volume phlebotomy tubes, point-of-care analysis and closed, no-waste sampling systems may contribute to the reduction in anemia.[78]

Approximately 70% of critically ill patients are transfused and receive their initial transfusion within the first 48 hours in the ICU.[76] For those patients staying greater than a week in the ICU about 73 to 85% of them will receive red cell transfusions.[71,76] The benefits of red cell transfusions must be weighed against such risks as immunosuppression, allergic reactions and infectious transmissions.[76] Higher transfusion rates have been reported to be associated with increased ICU length of stay, higher rates of coagulation abnormalities, more severe organ failure as well as increased mortality rates.[76,81,82] In light of these risks, alternative treatment strategies have been explored in critically ill patients such as the administration of exogenous human recombinant erythropoietin which has not been reported to result in a decrease in red cell transfusion. Erythropoietin is associated with more thrombotic events.[85-87] There are no widely accepted treatment guidelines for managing anemia in critically ill patients and practice varies between centers. Further research and understanding of anemia, in addition to innovative treatment strategies may promote improved clinical outcomes for critically ill patients.[75]

Indications for Red Blood Cell Transfusion in the ICU

In patients with hemorrhagic shock, initial resuscitation should be done using crystalloids. If the shock is not corrected after 2L of crystalloids, Packed Red Blood Cell (PRBC) transfusion is indicated to improve oxygen delivery to the tissues and should be guided by hemodynamic parameters rather than Hgb measurement.[88] Aggressive measures to control bleeding should accompany resuscitation. Blood lactate levels can be used to guide the adequacy of resuscitation.[89] In patients with hemodynamically stable anemia, transfusion is indicated if the Hgb level drops below 7g/dL and should be guided by the patient's condition rather than the absolute number.[82, 90] Transfusion to improve Hgb > 9 g/dL is not indicated in mechanically ventilated patients, patients with stable coronary disease and stable trauma patients. Transfusion to increase Hgb level > 8g/dL is indicated in patients with acute coronary symptoms. Whenever possible, transfusion should be given in single units.[91]

Massive transfusions, defined as transfusion to replace entire blood volume in 24 hours, are necessary in patients with hemorrhagic shock; however such transfusions are associated with hypothermia, metabolic acidosis and coagulopathy. Hypothermia occurs due to transfusion of stored cold blood and impairment of metabolism leading to delayed clearing of toxins and cytokines. Dilutional coagulopathy along with consumption coagulopathy occurs in these patients and this is further exacerbated by hypothermia that can occur with massive transfusions. A transfusion ratio of 1:1:1 (RBC, fresh frozen plasma, platelets) or whole blood is recommended in case of massive transfusions. Massive transfusions are also associated with hyperkalemia, hypocalcemia, hypomagnesemia, metabolic alkalosis and acidosis.[92] Transfusion associated acute lung injury (TRALI) occurs within 6 hours of transfusion with signs and symptoms of acute respiratory failure. The proposed mechanisms are reaction of donor antibodies against the recipient white blood cells (WBCs) and pulmonary vascular endothelial activation leading to WBC sequestration and endothelial damage.

Thrombocytopenia

Thrombocytopenia occurs frequently in critically ill patients and is the most common coagulation problem in this group of patients.[93,94] Approximately, 50% of critically ill patients may not present with thrombocytopenia at the time of admission into ICU, however, whether present on admission or developing during the ICU course, thrombocytopenia in critically ill patients suggests poor prognosis.[93,94] Depending on the cut off level utilized to define thrombocytopenia (i.e. $<150 \times 10^9$/L vs $< 100 \times 10^9$/L), the type of population being assessed (e.g. medical vs surgical/trauma) and the period of the ICU course (e.g. < 4 days vs ≥ 4 days) being studied, the incidence of thrombocytopenia has been reported to range from 15 to 60%.[94-96] The decreased risk of bleeding with platelet counts between 100 and 150×10^9/L has resulted in a cut off level of $< 100 \times 10^9$/L being proposed as the definition of thrombocytopenia in the critically ill.[94] In addition to increased bleeding risks and consequent necessity for transfusions, thrombocytopenia has also been associated with an increased length of ICU and hospital stay, as well as an increased mortality.[94,96] Not only has the severity of thrombocytopenia been independently associated with a poorer outcome, but the degree of decline in platelet count (i.e. 30 to 50%) over time has also been associated with a higher mortality, even if it remains within the normal range.[93,95,97] The relationship between a low or declining platelet count and mortality is doubtful to be causal but rather influenced by the disease or factors contributing to the development of thrombocytopenia.[93] These etiological factors include but are not limited to sepsis, organ failure, drugs, disseminated intravascular coagulation (DIC), nutritional deficiencies and tranfusion.[96] The mechanisms which may elucidate the development of thrombocytopenia are: spurious (e.g. laboratory error), disorders of distribution (e.g. splenomegaly) and dilution (e.g. massive transfusions), increased platelet destruction (e.g. DIC) and decreased platelet production (e.g. drugs).[94,96] Correction of the underlying cause may contribute to improving platelet counts and consequently prevent delays in required invasive procedures as well as limit the use of platelet transfusions.[94] Heparin induced thrombocytopenia (HIT), an antibody mediated reaction against platelet factor 4 occurs approximately 4 days after initiation of treatment and is associated with thrombotic rather than bleeding risk. Diagnosis is suspected when platelet count decreases by 50% from initial value. Treatment is with thrombin inhibitors– argatroban, hirudin or danaparoid– until platelet count reaches $> 150 \times 10^9$/L.[98]

Clinical Features

The signs and symptoms of thrombocytopenia tend to take place rapidly as platelets have a relatively short 10 day half-life.[83] The type of bleeding may be comparatively mild as in mucosal or cutaneous bleeding, e.g.

TABLE 133.11: The degree of thrombocytopenia and associated bleeding

Platelet count (cells × 10^9/L)	*Risk*
< 100	10-fold increased bleeding risk compared to platelet counts 100 to 150
< 50	Invasive procedures commonly avoided (Surgical bleeding uncommon if platelet counts >50)
< 20	Risk of spontaneous bleeding
< 10	Risk of severe, life-threatening bleeding

epistaxis, gingival bleeding and petechiae, or more severe as in spontaneous intracerebral hemorrhage.[83,94] The risk of bleeding depends on the degree of thrombocytopenia (Table 133.11).[94]

Diagnosis

The evaluation of a patient with thrombocytopenia involves a complete history and physical examination, assessing for what may be contributing to or causing the patient's low platelets such as splenomegaly, recent infections, co-morbidities or medications the patient may be taking or recently have taken. A peripheral blood smear can be essential in also determining the etiology of the patient's thrombocytopenia (Table 133.12).[94]

Management

Platelet concentrates are made by centrifugation of either whole blood or plasma and by apheresis of blood. Simply transfusing patients with platelets to raise levels may be unwarranted, ineffective and even contraindicated in some critically ill thrombocytopenic patients. It is essential to determine the typically multifactorial etiology of thrombocytopenia in these patients and subsequently correct the underlying cause (Table 133.13).[94] This usually results in the increase of platelet counts and possibly limits exposure to the risks of platelet transfusions as well as prevent delays in required invasive procedures.[94] Prophylactic platelet transfusion is given to patients who are actively bleeding with thrombocytopenia or when platelet counts fall below 10 × 10^9/L. The dose for prophylactic transfusion of platelets is controversial. In a recent study published in the New England Journal of Medicine, low, medium or high dose platelet transfusion did not differ in the incidence of bleeding.[99] Therapeutic transfusion is given to patients with thrombocytopenia associated with gross hemorrhage. Usually this bleeding is multifactorial and may not be corrected with platelet transfusion alone. In patients who require interventions, a platelet count > 50 × 10^9/L for trauma and general surgery and >100 × 10^9/L for neurological interventions is required.[100] Each platelet concentrate should produce an increase in platelet count of approximately 5 to 10 × 10^9/L

TABLE 133.12: Possible peripheral blood smear findings and their corresponding etiology and initial diagnostic step[94]

Smear	*Possible etiology*	*Diagnostic step*
Normal	Hypersplenism	Physical exam; imaging test
	Immune-mediated (drugs)	Review medications
	Idiopathic thrombocytopenic purpura (ITP)	Diagnosis of exclusion
Platelet clumping Platelet satellitism	Pseudo-thrombocytopenia	Re-draw specimen in heparin or citrate tube; repeat manual or automated count
Fragmented red blood cells (Schistocytes, helmet cells)	Microangiopathic hemolytic anemia*	Further evaluation based on suspected etiology
Atypical lymphocytes	Viral infection	Viral studies ± further evaluation based on suspected etiology
Oval macrocytes		
Hyperpigmented polymorphonuclear cells	Vitamin B_{12} deficiency Folate deficiency	Check vitamin B_{12} and folate levels
Leukoerythroblastosis	Myelophthisis	Bone marrow biopsy
Blasts	Leukemia

Dyserythropoiesis		
Dysgranulopoiesis	Myelo-dysplastic syndrome	Bone marrow biopsy
Dysmegakaryopoiesis		
White blood cell left shift	Sepsis	Septic work up

*Microangiopathic hemolytic anemia–Thrombotic thrombocytopenic purpura (TTP), Hemolytic uremic syndrome (HUS), Disseminated intravascular coagulation (DIC), Malignant Hypertension, Pre-eclampsia/eclampsia, HELLP syndrome (Hemolysis, elevated liver enzymes, low platelets), disseminated carcinoma, malfunctioning prosthetic heart valve, vasculitis, scleroderma renal crisis.

TABLE 133.13: The different causes, mechanisms and treatment of thrombocytopenia

Mechanism	*Pathophysiology*	*Etiology*	*Treatment*
Spurious	Clumping of platelets in specimen tube	Laboratory order	Specimen redrawn in heparin or citrate tube
Decreased platelet production	Bone marrow suppression	Nutritional deficiency Drugs; toxins Viral infections Metastases	Replete deficiencies Stop offending agent Supportive care Chemotherapy; radiation therapy
Increased platelet destruction	Non-immune-mediated	DIC	Treat underlying etiology; anticoagulation
		TTP	Plasma exchange
		HELLP	Delivery of infant
	Immune-mediated	Drugs	Stop offending drug
		Type 2 HIT	Stop heparin administration; start direct thrombin inhibitor
		ITP	Steroids; IV Ig; Splenectomy
Dilutional	Infusion of massive amounts of blood products and intravenous fluids	Transfusion for massive blood loss	Platelet transfusion; supportive care
Distributional	Increased platelet sequestration	Splenomegaly; portal hypertension	Supportive care; splenectomy

TTP: Thrombotic thrombocytopenic purpura, DIC: Disseminated intravascular coagulation, HELLP syndrome: Hemolysis, elevated liver enzymes, low platelets, HIT: Heparin-induced thrombocytopenia, ITP: Idiopathic thrombocytopenic purpura.
Adapted from Rice et al.[19]

in an average 70 kg adult. Refractoriness to platelet transfusion may be due to alloimmunization or non-immune factors. Alloimmunization can be prevented by giving ABO matched platelets and HLA compatible donors. Splenectomy may also improve thrombocytopenia in some cases. In patients with life-threatening bleeding and platelet refractoriness, giving frequent small transfusions, intravenous IgG administration, use of antifibrinolytic agents and transfusion of factor VIIa may be helpful.[101,102]

Risks of Transfusion

The administration of blood products is not without risk. These risks could be infectious or immune-mediated in nature (Table 133.14), but the greatest risk results from human error.[103-106] Although the incidence of infectious and immune-mediated events such as ABO incompatibililty has been on the decrease, in recent times the transfusion of blood products has been associated with organ dysfunction, immunosuppression, increased ICU stay and decreased survival.[73,76,82,94,96] Significant progress has been made in diminishing the risks, particularly infectious risks, associated with the transfusion of blood products. Early recognition of adverse events associated with transfusion is vital for patient's safety. Nevertheless, the accumulating body of clinical evidences suggest that the past assumptions of transfusions regularly providing effective therapy for anemia or thrombocytopenia can no longer be adhered to.[107] Transfusion practices vary from country to country and even from center to center within the same country. This has restricted advancement in identifying the best transfusion practice.[108]

Coagulopathy in the Intensive Care Unit

Coagulopathy occurs in critically ill patients due to the underlying illness or medications. There is no recommendation to transfuse patients with coagulopathy if they are not actively bleeding. Fresh frozen plasma is indicated for the replacement of single coagulation factor deficiency, multiple factor deficiencies, for patients with DIC associated with bleeding, during plasma exchange in patients with thrombotic thrombocytopenic purpura and for severe bleeding associated with warfarin-induced coagulopathy. Cryoprecipitate is given to patients when plasma fibrinogen levels are < 1 g/L. Recombinant factor VIIa is used in patients with hemophilia and factor VIII and factor IX inhibitors.

TABLE 133.14: The infectious and non-infectious complications of blood transfusion[105,106,108]

Infectious	HIV	**Non-infectious**	Febrile reactions
	Hepatitis A, B and C virus		Allergic • Urticarial/cutaneous reaction • Anaphylaxis

	Parasites • Plasmodium • Babesia • Trypanosoma		Circulatory overload
	Other viruses • HTLV types I and II • CMV • EBV		Allo-immunization • Red blood cell mediated • Human leukocyte antigen mediated
	Emerging infections • Creutzfeldt-Jakob disease • West nile virus • B19 Parvovirus		TRALI GVHD Transfusion related iron overload Transfusion related Immunomodulation

Abbreviations: CMV – Cytomegalovirus, EBV – Epstein-Barr virus, TRALI – Transfusion associated lung injury, GVHD – Graft-versus-host disease, HIV–Human immunodeficiency virus, HTLV–Human T-cell lymphotropic virus.

RENAL DISEASE IN CRITICAL CARE

Acute Kidney Injury

A normally functioning kidney eliminates urea and other nitrogenous waste products, in addition to regulating fluid, electrolyte and acid-base equilibrium.[109] Conversely, renal dysfunction results in the build-up of uremic toxins and nitrogenous waste products (azotemia) as well as an imbalance in the fluid, electrolyte and acid-base equilibrium, as a consequence of reduction in the Glomerular Filtration Rate (GFR).[110] Acute Kidney Injury (AKI), formerly referred to as acute renal failure, is said to occur when renal dysfunction takes place suddenly and/or rapidly.[111,112] Various definitions for AKI have been reported in the literature,[113,114] resulting in wide-ranging incidence and mortality rates of 1 to 25% and 15 to 90% respectively in intensive care units.[109,115-123] The need for a consensus definition for AKI resulted in the development of the RIFLE classification (Table 133.15) by the Acute Dialysis Quality Initiative (ADQI) group,[114,124-126] which was later modified by the Acute Kidney Injury Network (AKIN) to comprise smaller increases in serum creatinine, introduction of a time frame (48 hours) to the diagnosis of AKI and the elimination of Loss and End-stage renal disease as categories (Table 133.15).[127] Both classifications are associated with increased mortality with worsening degrees of AKI. The change in nomenclature to AKI now encompasses a broader spectrum of disease with different levels of severity, ranging from minor renal dysfunction to total organ failure necessitating renal replacement therapy.[109,112,116]

The etiology of AKI has typically been separated into three categories:

1. Pre-renal
2. Intrinsic renal
3. Post-renal azotemia (Table 133.16)[111]

So, it guides the mode of therapeutic intervention. However, in ICU patients, etiology of AKI is usually a result of multiple factors which could easily fall into any or more commonly, a combination of the aforementioned categories, thus complicating the manner in which such patients can be treated successfully.[112]

TABLE 133.15: The RIFLE and AKIN classification of acute kidney injury

	GFR criteria	*Urine output criteria*
RIFLE category		
Risk	Increased serum creatinine × 1.5 or GFR decrease > 25%	UO < 0.5 ml/kg/h × 6h
Injury	Increased serum creatinine × 2 or GFR decrease > 50%	UO < 0.5 ml/kg/h × 12h
Failure	Increased serum creatinine × 3 or GFR decrease > 75% or serum creatinine ≥ 4 mg/dl (with acute rise ≥ 0.5 mg/dl)	UO < 0.3 ml/kg/h × 24h or Anuria × 12h
Loss	Persistent ARF → complete loss of renal function > 4 weeks	
ESRD	End-stage renal disease → complete loss of renal function > 3 months	
AKIN stage		
1	Increased serum creatinine ≥ 0.3 mg/dl (≥ 26.4 μmol/l) or increase ≥ 150% to 200% (1.5- to 2- fold) from baseline	UO < 0.5 ml/kg/h for > 6h
2	Increased serum creatinine > 200% to 300% (>2- to 3-fold) from baseline	UO < 0.5 ml/kg/h for > 12h
3	Increased serum creatinine > 300% (3-fold) from baseline or serum creatinine ≥ 4.0 mg/dl with an acute increase of at least 0.5 mg/dl	UO < 0.3 ml/kg/h for > 24 h or anuria for 12 hours

Abbreviations: GFR: Glomerular filtration rate; UO: Urine output; ARF: Acute renal failure; ESRD: End-stage renal disease; AKIN: Acute kidney injury network; RIFLE: Risk, injury, failure, loss, ESRD.
Adapted from Bellomo R et al.[126] and Mehta RL et al.[127]

TABLE 133.16: Various causes of acute kidney failure in intensive care unit[111]

Pre-renal		*Intrinsic*		*Post-renal*
	Acute tubular necrosis	Glomerulonephritis	Interstitial nephritis	
Sepsis*	Hypotension/shock	Post-infectious GN	Medications (NSAID, antibiotics, diuretics)	Bladder neck obstruction (prostate disease)

Medications (diuretics, NSAID)	Rhabdomyolysis	Goodpasture's syndrome	Immunologic causes	
Burns	Medications (antibiotics, antivirals, antifungals, radiocontrast dye)	Rapidly progressive GN		Neurogenic bladder
Surgery (cardiac, vascular)	Burns	Medications (NSAID, biphosphonates)		
Shock (anaphylactic, hemorrhagic, hypovolemic)	Transfusion reactions Hemolysis Tumor lysis syndrome			
Hepatorenal syndrome				
Abdominal compartment syndrome				

Abbreviations: GN: Glomerulonephritis; GI: Gastrointestinal; NSAID: Non-steroidal anti-inflammatory drug.
*Sepsis is the most common cause of acute kidney injury in the ICU in up to 50% of cases.
Adapted from Abuelo JG[111] and Bellomo R et al.[126]

Clinical Presentation

Acute kidney injury can affect multiple organ systems. The reduction in GFR and urine output can result in fluid overload which may further progress into congestive heart failure and hypotension, raised intra-abdominal pressure from retroperitoneal tissue edema and ascites, hypertension from intravascular volume overload as well as pulmonary compromise from congestion and pleural effusions.[128] Electrolyte abnormalities such as metabolic acidosis and hyperkalemia commonly occur predisposing to cardiac arrhythmias. Critically ill patients with AKI can also develop a compromised inflammatory and immune response which increases the risk for infection, pneumonia, shock or other multi-organ failure.[128] The uremic state in these patients can contribute to the development of anorexia, vomiting, encephalopathy, pericarditis, bleeding diathesis, polyneuropathy and anemia from increased erythrocyte destruction which can be further complicated by weakness and easy fatiguability.[128,129] These multiple adverse effects contribute to the increased mortality in critically ill patients with AKI.

Diagnosis

The diagnosis of AKI involves taking a detailed clinical history, physical examination and the performance of relevant tests which may aid in determining the etiology such as, Blood Urea Nitrogen (BUN), serum creatinine, urine microscopy, urine chemistry and renal ultrasound.[112,130] The serum creatinine is a commonly used tool in diagnosing AKI; however, it is important to note that like all approximations of GFR, it is not an accurate reflection of the latter in ICU patients who tend to be in a non-steady state. In such patients, it tends to underestimate the degree of renal dysfunction such that large changes in GFR are mirrored by only small changes in the serum creatinine.[112,118] Nonetheless, it is the change in serum creatinine that provides clinical benefit in diagnosing AKI. Urine chemistries such as the fractional excretion of sodium and urea (Table 133.17) may help in distinguishing pre-renal from renal causes of AKI (Table 133.18); although in ICU patients these tend to co-exist.[112,130] Finally, due to limitations of the aforementioned diagnostic tools, AKI biomarkers such as cysteine-rich protein 61, neutrophil gelatinase-associated lipocalin, kidney injury molecule-1, cystatin C and urine interleukin-18, are actively being investigated as alternatives for the earlier detection of AKI prior to functional deterioration.[109,112,130]

TABLE 133.17: The calculation formulas for the fractional excretions of sodium and urea

Fractional excretion of sodium

$FE_{Na} = \{(U_{Na} / P_{Na}) \div (U_{Cr} / P_{Cr})\} \times 100$

Fractional excretion of urea*

$FE_{Ur} = \{(U_{Ur} / P_{Ur}) \div (U_{Cr} / P_{Cr})\} \times 100$

Abbreviations: FE_{Na}: Fractional Excretion of Sodium; U_{Na}: Urine Sodium Concentration (mEq/L); P_{Cr}: Plasma Creatinine Concentration (mg/dL); U_{Cr}: Urine Creatinine Concentration (mg/dL); P_{Na}: Plasma Sodium Concentration (mEq/L); FE_{Ur}: Fractional Excretion of Urea; U_{Ur}: Urine Urea Concentration (mg/dL); P_{Ur}: Plasma Urea Concentration (mg/dL).

*Provides information similar to the fractional excretion of sodium, but in contrast, can be used in patients on diuretic therapy.

Management

The treatment of ICU patients with AKI can be challenging as the majority of these patients develop AKI from multiple precipitating factors and commonly have co-existing multiorgan failure.[110,112] Nonetheless, treatment strategies are initially targeted at correcting the suspected underlying cause. Such treatment may include but is not limited to fluid resuscitation with or without inotropic or vasopressor support to maintain hemodynamic stability and renal perfusion, correction of metabolic abnormalities, discontinuation of nephrotoxic agents or dosage adjustments of medications eliminated through the kidney, as well as the provision of adequate nutrition.[112,130]

With regards to fluid resuscitation, there is no difference in survival when comparing crystalloids with colloids (albumin).[131] In patients with head trauma, colloid resuscitations have been found to increase mortality.[132] In addition, synthetic colloids are associated with an increased incidence of kidney injury, especially

TABLE 133.18: Delineation of laboratory features for differentiating pre-renal and renal causes of acute kidney injury

Urinary diagnostic indices	*Pre-renal*	*Renal*
BUN:Cr ratio	> 20:1	< 20:1
Urine sodium (mEq/L)	< 20	> 40
FE_{Na} (%)	< 1	> 2
FE_{Ur} (%)	< 35	> 50
Urine osmolality (mOsm/L)	> 500	< 350
Urine microscopy	Normal (except for occasional hyaline casts)	Abnormal

Abbreviations: BUN: Blood urea nitrogen; Cr: Creatinine; FE_{Na}: Fractional excretion of sodium; FE_{Ur}: Fractional excretion of urea the large molecular preparations used for resuscitation.[133,134] Furthermore, though fluid resuscitation can be crucial in these patients, a positive fluid balance is also associated with an increased mortality.[135]

The role of diuretic agents in the treatment of AKI remains controversial.[112] Diuretics have not been found to improve overall mortality, need for renal replacement therapy or shorten the duration of AKI.[136] At the present time, there is no evidence supporting the routine use of diuretics in patients with AKI or to convert oliguric renal failure to nonoliguric renal failure. In addition, there is no consensus regarding the most appropriate time to start Renal Replacement Therapy (RRT) for AKI. However, severe hyperkalemia, severe metabolic acidosis, uremic complications such as encephalopathy, pericarditis, pleuritis or bleeding diathesis and volume overload are generally considered to be absolute indications for RRT, which could either be continuous or intermittent.[112]

Similarly, there is also no consensus regarding the dose of hemofiltration or the renal replacement modality, i.e. continuous versus intermittent. A detailed description of modes of renal replacement therapy is beyond the scope of this chapter.

Prevention of Acute Kidney Injury

Early recognition of underlying risk factors and prevention of additional injuries in high risk patients are particularly important. Maintaining adequate renal perfusion, prevention of hyperglycemia and avoidance of nephrotoxins are some of the strategies used for this purpose.

Radioiodine contrast-induced nephropathy can be prevented by using a low volume nonionic low osmolar or iso-osmolar agent in a well-hydrated patient. There is no significant advantage in using sodium bicarbonate over sodium chloride solution.[137] Prophylactic administration of N-acetyl cysteine to prevent renal failure is also controversial.[138,139] In patients who must undergo radiological studies utilizing contrast, adequate hydration, use of prophylactic N-acetyl cysteine, avoidance of other nephrotoxic agents and use of low volume non-ionic low or iso-osmolar agents are recommended.

Acute kidney injury is common in patients with hepatic failure admitted to ICUs. In cirrhotic patients requiring large volume paracentesis and in patients with spontaneous bacterial peritonitis, the administration of intravenous albumin decreases the incidence of AKI.[140] In patients with hepatorenal syndrome, use of a splanchnic vasoconstrictor like telipressin may improve kidney function.[141] Noradrenaline has also been reported to be as effective as telipressin in decreasing serum creatinine.[142] Similarly, other agents like octreotide and midodrine have been found useful in this condition.[143] Nonetheless, the definitive treatment for hepatorenal syndrome is liver transplantation.

In summary, acute kidney failure is common in critically ill patients and is associated with significant increase in mortality. Prevention of renal injury is important. Most of the treatment modalities are controversial and need further studies.

ENDOCRINE EMERGENCIES IN CRITICAL CARE

Patients with endocrine emergencies are uncommonly admitted to critical care units. The accurate and early diagnosis of these entities is absolutely important for better outcomes in these patients. In this section, we will discuss the clinical presentation, diagnosis and management of the common endocrine emergencies.

Thyroid Storm

Hyperthyroid patients present with palpitations, unexplained weight loss, diarrhea and intolerance to heat and muscle weakness. Thyroid storm is a hyperthyroid state where the symptoms are exaggerated and associated with 20 to 50% mortality. The common causes are Grave's disease, chronic and subacute thyroiditis, postpartum thyroiditis and excessive iodine intake. It can also be precipitated by stress, surgery, sepsis or cardiovascular events in a preexisting hyperthyroid patient.

Clinical and Diagnostic Features

Patients can present with cardiac arrhythmias, widened pulse pressure, congestive heart failure, systemic inflammatory response syndrome, hypotension, psychosis, delirium and coma. A scoring system based on the signs and symptoms seen in thyroid storm are shown in Table 133.19.[144] The laboratory findings specific to the thyroid gland include a low or undetectable Thyroid Stimulating Hormone (TSH) level and a high thyroxine (T4) level.

Management

The key is to start treatment as soon as the thyroid storm is clinically suspected. The therapeutic regimen involves the use of various agents. Patients should be stabilized with fluids if hypotensive or with diuretics in case of congestive heart failure. Adequate oxygenation should be maintained and often these patients may need mechanical ventilatory support. Fever should be controlled by cooling

TABLE 133.19: The scoring system for the clinical evaluation of a thyroid storm

Thermoregulatory dysfunction		**Cardiovascular dysfunction**	
Temperature		Tachycardia	
99-99.9	5	99-109	5
100-100.9	10	110-119	10
101-101.9	15	120-129	15
102-102.9	20	130-139	20
103-103.9	25	≥ 140	25
≥ 104.0	30	**Congestive heart failure**	
Central nervous system effects		Mild	5
Mild	10	Pedal edema	
Agitation		Moderate	10
Moderate		Bibasilar rales	
Delirium, Psychosis	20	Severe	
Extreme lethargy		Pulmonary edema	15
Severe		Atrial fibrillation	10
Seizure	30		
Coma		**Precipitant history**	
		Negative	0
		Positive	10
GI/Hepatic dysfunction		**Total score**	**Diagnosis**
Moderate			
Diarrhea, abdominal pain	10	≥ 45	More likely
Nausea/vomiting			
Severe	20	25 to 44	Suggestive
Unexplained jaundice		≤ 25	Less likely

Adapted from Burch HB et al.[144]

and the use of acetaminophen. Specific treatment initially involves the prevention of thyroid hormone synthesis by using thionamides. Either propylthiouracil or methimazole can be used. Propylthiouracil has the advantage of decreasing peripheral conversion of T4 to triiodothyronine (T3). Propylthiouracil is given at a dose of 200 mg every 4 hours and methimazole is given at a dose of 30 mg every 6 hours.[145] Unlike propylthiouracil, methimazole cannot be given in pregnancy. The serious side effects of thionamides are agranulocytosis (dose dependent), anti-neutrophil cytoplasmic antibody (ANCA) positive vasculitis and hepatic failure. The second step is to prevent the release of synthesized hormone from the thyroid gland. Lugol's iodine (10 drops, 3 times daily) or saturated solutions of potassium iodide [SSKI (5 drops every 6 hours)] is used for this purpose.[146] It is important to give iodine only after giving hormone synthesis blocking agents. Lithium carbonate also decreases the release of thyroid hormone but is rarely used due to its toxicity. The third step is to give agents to prevent conversion of T4 to T3. These include glucocorticosteroids and iodinated contrast solutions. The administration of beta- (β) blockers will counteract the sympathetic stimulation and propanolol is the drug of choice. It is given intravenously 1 mg/minute. Alternative agents are nadolol or esmolol. Patient with contraindications to β-blockers can be given calcium channel blockers as an alternative.

Myxedema Coma

Myxedema coma is a rare but life-threatening complication that results from severe untreated hypothyroidism or long standing hypothyroidism.[147] It can be precipitated by trauma, surgery, severe infection and cold stress especially with the usage of sedative, hypnotic and narcotic medications.[148]

Clinical and Diagnostic Features

Myxedema is characterized by distinct clinical features rather than by laboratory findings suggestive of

TABLE 133.20: The clinical features of myxedema coma based on the organ system involved

System	*Clinical features*
Neurological	Mental obtundation, delayed relaxation phase of reflexes
Cardiovascular	Bradycardia, hypotension, EKG changes, pericardial effusions
Endocrine	Hypoglycemia, hyponatremia, hypothermia
Respiratory	Hypoventilation, pleural effusions
Gastrointestinal	Paralytic ileus, ascites
Genitourinary	Atonic bladder, urinary retention
Integumentary	Alopecia, coarse dry skin, myxedema facies

hypothyroidism. Clinical features of myxedema coma are outlined in Table 133.20.

The role of laboratory findings is to confirm the diagnosis and delineate co-existing or precipitating conditions. Low TSH levels along with low total and free serum T4 and T3 levels are noted in primary hypothyroidism. High TSH levels with below normal levels of T3 are seen in secondary hypothyroidism. Low sodium levels with elevated levels of lactate dehydrogenase (LDH) and creatinine are also seen.

Management

Because of the high mortality associated with this condition, patients should be monitored in the ICU.[149] Supportive care, treatment of hypothermia, monitoring of the neurological and respiratory status should be emphasized along with the supplementation of thyroid hormones.[150,151] Treatment is outlined in Table 133.21. The optimal dose of thyroid replacement remains controversial.

Both thyroid storm and myxedema coma are associated with significant mortality and early recognition and treatment are important for a favorable outcome.

TABLE 133.21: The management of myxedema coma in a critical care setting

Supportive care	• Invasive mechanical ventilation to bypass mechanical obstruction caused by large tongue • Fluid and vasopressor administration for hypotension • Passive re-warming for hypothermia • Stress dose corticosteroids for possible co-existing adrenal insufficiency • Monitoring and correction of electrolyte abnormalities
Replacement of thyroid hormone	• Both T4 and T3 given intravenously • Bolus of 300-500 μg followed by 50-100 μg daily • Use caution in elderly patients and patients with myocardial injury • Pregnant patients may need higher doses
Management of co-existing conditions	• Panculture and initiation of broad-spectrum antibiotics

Acute Adrenal Insufficiency

Acute adrenal insufficiency is seen in patients with bilateral adrenal hemorrhage, undiagnosed adrenal insufficiency with stress, trauma, surgery, drugs especially etomidate and previous steroid therapy, and pituitary apoplexy.[152-154] The clinical and laboratory features associated with acute adrenal insufficiency or adrenal crisis are outlined in Table 133.22.

Diagnosis is difficult due to diurnal variation of cortisol secretion. Cortisol levels are higher in the morning and lower in the evening. A cortisol level of less than 3 mcg/dL in the morning is diagnostic of adrenal insufficiency and a level less than 10 mcg/dL is suggestive of the diagnosis.[155] The Adrenocorticotropic Hormone (ACTH) stimulation test is used to establish a definitive diagnosis. In cases of suspected adrenal crisis, treatment with hydrocortisone or dexamethasone should be started immediately and not delayed by confirmatory tests. The supportive measures include volume administration with isotonic fluids with glucose in case of hypoglycemia. Precipitating causes must be sought and treated. Management of adrenal insufficiency in patients with septic shock will be described elsewhere.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

Diabetic Ketoacidosis (DKA), hyperosmolar Hyperglycemic State (HHS) and drug-induced hypoglycemia

TABLE 133.22: The clinical and laboratory findings that can be seen in patients with adrenal crisis

- Dehydration, hypotension or shock out of proportion to severity of current illness
- Nausea and vomiting with a history of weight loss and anorexia
- Abdominal pain (acute abdomen)
- Unexplained hypoglycemia
- Unexplained fever
- Hyponatremia, hyperkalemia, azotemia, hypercalcemia, or eosinophilia
- Hyperpigmentation or vitiligo
- Other autoimmune endocrine deficiencies, such as hypothyroidism or gonadal failure

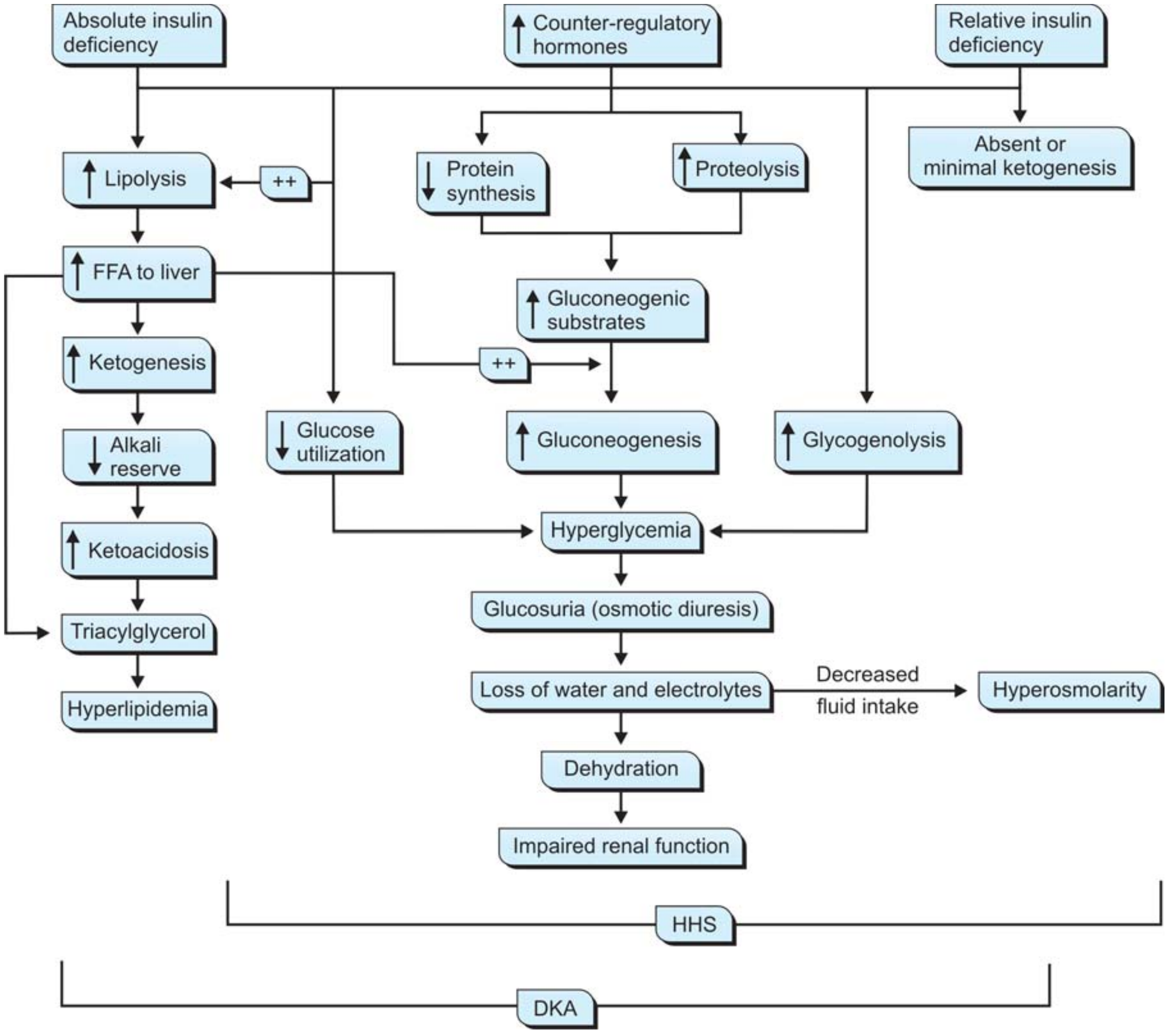
are the major complications of diabetes mellitus. Both DKA and HHS are due to insulin deficiency and excessive counter-regulatory hormones. A detailed description of the pathogenesis is beyond the scope of this chapter, however, a synopsis is demonstrated in Figure 133.5.[156] The precipitating factors contributing to the development of DKA and HHS are also outlined in Table 133.23.[156]

Clinical and Diagnostic Features

DKA and HHS patients usually present with nausea, vomiting, abdominal pain, shortness of breath, polyuria and polydipsia. As the condition worsens they develop neurological symptoms which may progress to coma. The initial evaluation should assess hemodynamic status and airways. The investigations to be performed include WBC count, complete metabolic panel, plasma osmolality, urine analysis, serum and urine ketones, arterial blood gases, electrocardiogram (ECG) and Chest X-ray (CXR). The characteristic findings and differences are described in Table 133.24.[157] Metabolic acidosis is the hallmark of DKA. Other causes of metabolic acidosis are outlined in Table 133.25.[156]

Management

A management algorithm is described in Figure 133.6.[158] These patients should be managed in the ICU. If potassium is less than 3 mEq/L, replenish potassium to above 3.3 mEq/L before initiating insulin. Sodium bicarbonate is given only when the arterial pH is less than 7. The insulin infusion is typically continued until ketoacidosis is resolved. Blood glucose should be



Absolute insulin deficiency
↑ Counter-regulatory hormones
Relative insulin deficiency
↑ Lipolysis
++
↓ Protein synthesis
↑ Proteolysis
Absent or minimal ketogenesis
↑ FFA to liver
↑ Gluconeogenic substrates
↑ Ketogenesis
++
↓ Alkali reserve
↓ Glucose utilization
↑ Gluconeogenesis
↑ Glycogenolysis
↑ Ketoacidosis
Hyperglycemia
Glucosuria (osmotic diuresis)
Triacylglycerol
Loss of water and electrolytes
Decreased fluid intake
Hyperosmolarity
Hyperlipidemia
Dehydration
Impaired renal function
HHS
DKA

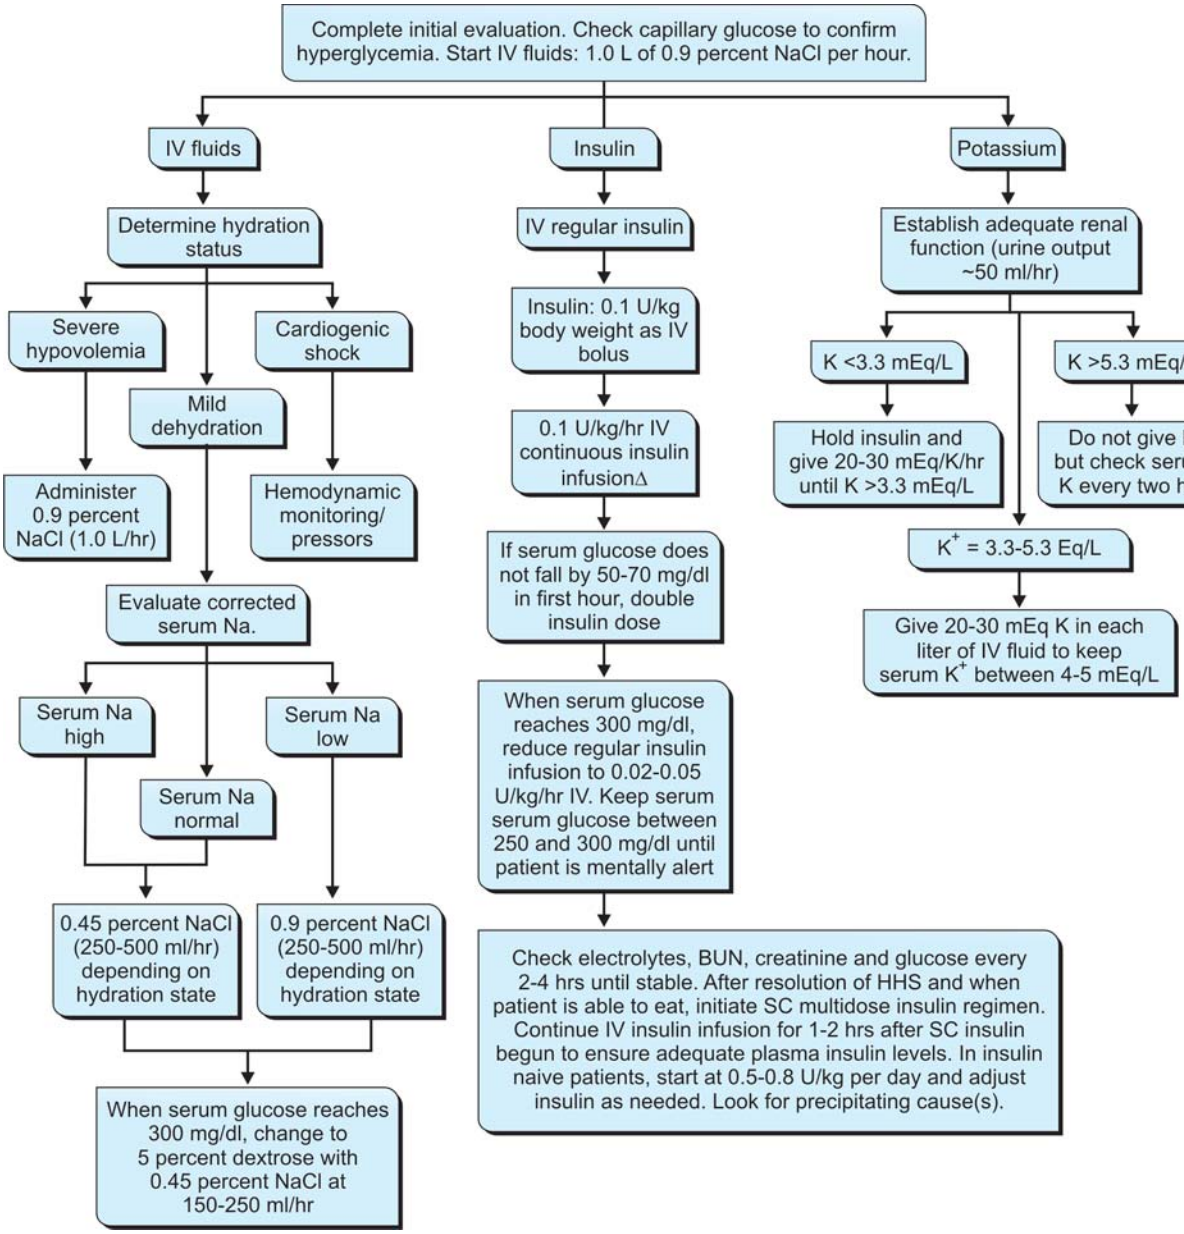
Acetest and Ketostix measure acetoacetic acid only - values obtained may be misleading low because the majority of ketone bodies are β-hydroxybutyrate; + Positive; • Respiratory alkalosis/metabolic acidosis; ∆ May get false-positive or false-negative urinary glucose caused by the presence of salicylate or its metabolites.

Kitabchi AE et al.[156]



Complete initial evaluation. Check capillary glucose to confirm hyperglycemia. Start IV fluids: 1.0 L of 0.9 percent NaCl per hour.
IV fluids
Insulin
Potassium
Determine hydration status
IV regular insulin
Establish adequate renal function (urine output ~50 ml/hr)
Severe hypovolemia
Cardiogenic shock
Mild dehydration
Insulin: 0.1 U/kg body weight as IV bolus
K <3.3 mEq/L
K >5.3 mEq/L
Administer 0.9 percent NaCl (1.0 L/hr)
Hemodynamic monitoring/ pressors
0.1 U/kg/hr IV continuous insulin infusionΔ
Hold insulin and give 20-30 mEq/K/hr until K >3.3 mEq/L
Do not give K but check serum K every two hrs
If serum glucose does not fall by 50-70 mg/dl in first hour, double insulin dose
K⁺ = 3.3-5.3 Eq/L
Evaluate corrected serum Na.
Give 20-30 mEq K in each liter of IV fluid to keep serum K⁺ between 4-5 mEq/L
Serum Na high
Serum Na low
Serum Na normal
When serum glucose reaches 300 mg/dl, reduce regular insulin infusion to 0.02-0.05 U/kg/hr IV. Keep serum serum glucose between 250 and 300 mg/dl until patient is mentally alert
0.45 percent NaCl (250-500 ml/hr) depending on hydration state
0.9 percent NaCl (250-500 ml/hr) depending on hydration state
Check electrolytes, BUN, creatinine and glucose every 2-4 hrs until stable. After resolution of HHS and when patient is able to eat, initiate SC multidose insulin regimen. Continue IV insulin infusion for 1-2 hrs after SC insulin begun to ensure adequate plasma insulin levels. In insulin naive patients, start at 0.5-0.8 U/kg per day and adjust insulin as needed. Look for precipitating cause(s).
When serum glucose reaches 300 mg/dl, change to 5 percent dextrose with 0.45 percent NaCl at 150-250 ml/hr

Fig. 133.6: An algorithm on the management of patients with hyperosmolar hyperglycemic non-ketotic syndrome and diabetic ketoacidosis.
Abbreviations: IV: intravenous; SC: subcutaneous.
Umpierrez GE et al.[158]

monitored every hour while on an insulin infusion while other laboratory tests, i.e. basic metabolic profile are monitored every 3 to 4 hours. The complications of untreated DKA and HHS are cerebral edema particularly in children and noncardiogenic pulmonary edema.[157,159] Patients must be monitored for hypoglycemia and hypokalemia. Almost all patients with DKA develop a non-anion gap metabolic acidosis with treatment and phosphate repletion is not recommended for patients with DKA.[160]

Hypoglycemia in diabetic patients occurs either due to insulin excess or as a result of failure of the counter regulatory hormones. Symptoms and signs are usually non-specific. Severe hypoglycemia causes seizure and coma and should be treated with glucagon 0.5 to 1mg subcutaneous or intramuscularly as well as intravenous glucose (dextrose).

NEUROLOGICAL DISORDERS IN CRITICAL CARE

Acute Ischemic Stroke

A stroke is a focal neurological deficit that is typically of acute onset and results from a disruption of the cerebral blood flow. It usually occurs suddenly, but occasionally progresses in a more gradual fashion. The majority of stroke presentations result from cerebral ischemia, while hemorrhage (intra-cerebral or subarachnoid) cause the rest.[161] Acute ischemic stroke is being discussed here while intra-cerebral and subarachnoid hemorrhages are discussed in subsequent sections. The mechanisms causing ischemic strokes could be grouped into atherothrombotic, cardioembolic, lacunar and cryptogenic types (Table 133.26).[162,163] Strokes may result in permanent disability and prognosis tends to be poorer in older patients, as well as patients with underlying co-morbidities such as diabetes or heart disease.[161,164] Time is of the essence in the management of these patients. The advent and widespread utilization of thrombolytic therapy within 3 hours of developing ischemic stroke, has revolutionized the management of what was once considered a condition with few treatment choices.[165]

TABLE 133.26: The different pathophysiological mechanisms contributing to the development of ischemic stroke

Pathophysiology	*Frequency of ischemic stroke*
Atherosclerotic cerebrovascular disease	
Hypoperfusion	
Arteriogenic emboli	20%
Lacunar (small penetrating artery disese)	
Arterial thrombosis 2^o atheroma formation or lipohyalinosis	25%
Cardiogenic embolism	
Atrial fibrillation	
Valvular heart disease	
Atrial or ventricular thrombi	20%
Atrial myxoma	
Bacterial endocarditis	
Cryptogenic	30%
Other	
Prothrombotic states	
Dissections	5%
Arteritis	
Migraines/vasospasms	
Drug abuse	

Adopted from Albers et al.[162,163]

Clinical Features

Thrombotic strokes tend to present with clinical features that evolve over hours to days whereas embolic strokes have a sudden or rapid onset at maximum severity at the time or presentation. The pattern of neurological impairment will depend on the vascular territory involved (Table 133.27).

Diagnosis

It is essential to obtain a comprehensive history, particularly determining the time of symptom onset, any recent events like trauma, surgery, myocardial infarction or prior stroke, medication use such as anticoagulants, insulin or anti-hypertensives, and evaluation of other co-morbidities which are present.[166] A complete physical examination with emphasis on the neurological system should also be performed when a patient presents with a neurological deficit suggestive of an ischemic event.

TABLE 133.27: The clinical presentation of acute ischemic stroke in relation to the vascular region involved

Vascular territory	*Neurological deficit*
Anterior cerebral artery	Contralateral hemiparesis and hemisensory deficit (leg > arm), urinary incontinence, abulia, confusion, primitive reflexes (sucking, grasp), apraxia.
Middle cerebral artery	Contralateral hemiparesis and hemisensory deficit (face and arm > leg and foot), homonymous hemianopsia, ipsilateral gaze preference, aphasia (Broca's and Wernicke) with dominant (left-sided) hemisphere lesion, neglect with non-dominant (right-sided) hemisphere lesion.
Posterior cerebral artery	Contralateral hemiparesis and hemisensory deficit, altered mental status, ophthalmoplegia from 3rd cranial nerve palsy, macular-sparing homonymous hemianopsia, visual agnosia, visual hallucinations, alexia without agraphia, disorders of color perception, amnesia.
Vertebrobasilar	Deficits involve the medulla (medial or lateral medullary syndrome), pons (locked-in syndrome), midbrain and cerebellum; and consist of dysphagia, dysarthria, diplopia, dizziness, vertigo, nausea, vomiting, Horner's syndrome, cranial nerve palsies, limb and gait ataxia, motor and sensory deficits involving both parts of the body.
Lacunar	Pure hemiparesis, pure hemisensory deficit, ataxic hemiparesis, dysarthria-clumsy hand.

Certain conditions are known to mimic the clinical features of ischemic strokes and include but are not limited to intracranial bleeds, seizures with postictal paresis, syncope, systemic infection, brain tumors, complicated migraines, conversion disorders, hypertensive encephalopathy, hypothyroidism, hyperglycemia, hypoglycemia and hyponatremia.[161,165-167] It is important to distinguish these mimics from ischemic strokes so as to treat the patients appropriately. The National Institute of Health Stroke Scale (NIHSS) is a 42-point scale based on neurological deficits elicited on physical examination (Table 133.28).[168] It is commonly utilized to quantify the severity of the neurological deficit. Initial general tests to be performed include complete blood count, coagulation profile, serum electrolytes, serum glucose, renal function, electrocardiography and chest radiography.[161,165,167,169] Specific tests that are to be performed promptly are CT-scan or Magnetic Resonance Imaging (MRI) of the brain to distinguish the etiology and nature of the stroke, and later once the diagnosis is established, carotid duplex ultrasonography and transthoracic echocardiography with or without bubble contrast.[161,165,170]

Management

Time is of the essence and initial management at time of presentation involves stabilizing the patient, performing a prompt clinical evaluation, as well as laboratory and imaging studies, and thereby assessing the need for resuscitation, oxygen supplementation or intubation, fever, blood sugar or blood pressure control, and thrombolysis.[161,169] Fever, hyperglycemia and hypotension following an ischemic stroke have been associated with poorer outcomes and their treatment is being evaluated in randomized trials.[171-175] The National Institute of Neurological Disorders and Stroke Recombinant Tissue Plasminogen Activator (NINDS rt-PA) stroke trial demonstrated that ischemic stroke patients treated with thrombolysis using intravenous recombinant tissue plasminogen activator (rt-PA) i.e. alteplase within 3 hours after the onset of symptoms were 31 to 50% more likely to have a better clinical outcome at 3 months in contrast to the 20 to 38% in those who received placebo, although there was no difference in mortality.[176] However, there is an associated risk of intracranial hemorrhage associated with thrombolysis.[176] Prevention of this complication is of the utmost importance, therefore only carefully selected patients who fulfill certain criteria (Table 133.29) can receive thrombolysis.[166,170] Patients need to be monitored closely either in an ICU or stroke unit following thrombolysis, with vital sign checks every 15 minutes for 2 hours, then every 30 minutes for 6 hours and then every hour for 16 hours. Additionally, arterial punctures need to be avoided and all anti-platelet or anti-coagulation therapy should be withheld for the first 24 hours following rt-PA administration because of the increased risk of bleeding.[176] Stroke patients develop significant morbidity either as a result of the disease itself e.g. impaired swallowing, seizures, cerebral edema, infections such as pneumonia or urinary tract infection, or as a result of complications following treatment e.g. hemorrhagic transformation. The early recognition and appropriate treatment of these conditions, where possible, is essential in improving clinical outcome.

Subarachnoid Hemorrhage

Subarachnoid Hemorrhage (SAH) accounts for 10% of Cerebrovascular Accidents (CVAs) and is associated with significant morbidity and mortality (50%). Subarachnoid hemorrhage may be spontaneous or traumatic.[177] The spontaneous causes of SAH are delineated in Table 133.30. The risk factors for SAH include cigarette smoking, heavy alcohol consumption, uncontrolled hypertension, use of sympathomimetic drugs, cocaine abuse, estrogen deficiency and some hereditary conditions like polycystic kidney and Ehlers-Danlos syndrome.

Clinical Features

Patients present with unusual or severe sudden onset headaches. Warning bleeds and sentinel headaches are relatively uncommon. Physical examination may provide some indication to the location of the bleeding. Clinical features associated with SAH are delineated in Table 133.31.

Diagnosis

The initial screening test to confirm the diagnosis is a non-contrast CT-scan of the brain; however the diagnostic yield depends on the time that has elapsed between symptom onset to performance of the CT-scan (sensitivity 98% in first 12 hours and 54% at 5 days). Other conditions such as intracerebral hemorrhage, mass effect and hydrocephalus, which may present in a similar manner, can also be differentiated with the initial CT-scan. A false negative CT-scan can result from severe anemia or small volume hemorrhage. A lumbar puncture should be performed after an initial negative CT-scan and in SAH patients will display a high opening pressure, red blood cells in the CSF that do not clear and

TABLE 133.28: The NIH stroke scale (NIHSS). A score of ≥ 16 is associated with a high likelihood of severe disability or death, while a score of ≤ 6 is associated with a good prognosis

Entity	*Score*
1a. Level of Consciousness: A 3 is scored only if the patient makes no movement (other than reflexive posturing) in response to noxious stimulation.	0 = Alert; keenly responsive. 1 =Not alert; but arousable by minor stimulation to obey, answer, or respond. 2 = Not alert; requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid and areflexic.
1b. LOC Questions: The patient is asked the month and his/her age. The answer must be correct - there is no partial credit for being close	0 =Answers both questions correctly. 1 =Answers one question correctly. 2 =Answers neither question correctly.
1c. LOC Commands: The patient is asked to open and close the eyes and then to grip and release the non-paretic hand. Substitute another one step command if the hands cannot be used	0 = Performs both tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.
2. Best Gaze: Only horizontal eye movements will be tested. Voluntary or reflexive (oculocephalic) eye movements will be scored but caloric testing is not done	0 = Normal. 1 = Partial gaze palsy; gaze is abnormal in one or both eyes, but forced deviation or total gaze paresis is not present. 2 = Forced deviation, or total gaze paresis not overcome by the oculocephalic maneuver.
3. Visual: Visual fields (upper and lower quadrants) are tested by confrontation, using finger counting or visual threat, as appropriate. Patients may be encouraged, but if they look at the side of the moving fingers appropriately, this can be scored as normal. If there is a unilateral blindness or enucleation, visual fields in the remaining eye are scored.	0 = No visual loss. 1 = Partial hemianopia. 2 = Complete hemianopia. 3 = Bilateral hemianopia (blind including cortical blindness).
4. Facial Palsy: Ask – or use pantomime to encourage – the patient to show teeth or raise eyebrows and close eyes. Score symmetry of grimace in response to noxious stimuli in the poorly responsive or non-comprehending patient.	0 = Normal symmetrical movements. 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling). 2 = Partial paralysis (total or near-total paralysis of lower face). 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face).
5. Motor Arm: The limb is placed in the appropriate position: extend the arms (palms down) 90 degrees (if sitting) or 45 degrees (if supine). Drift is scored if the arm falls before 10 seconds. The aphasic patient is encouraged using urgency in the voice and pantomime, but not noxious stimulation. Each limb is tested in turn, beginning with the non-paretic arm. Only in the case of amputation or joint fusion at the shoulder, the examiner should record the score as untestable (UN), and clearly write the explanation for this choice.	0 = No drift; limb holds 90 (or 45) degrees for full 10 seconds. 1 = Drift; limb holds 90 (or 45) degrees, but drifts down before full 10 seconds; does not hit bed or other support. 2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity. 3 = No effort against gravity; limb falls. 4 = No movement. UN = Amputation or joint fusion 5a. Left Arm 5b. Right Arm
6. Motor Leg: The limb is placed in the appropriate position: Hold the leg at 30 degrees (always tested supine). Drift is scored if the leg falls before 5 seconds. The aphasic patient is encouraged using urgency in the voice and pantomime, but not noxious stimulation.	0 = No drift; leg holds 30-degree position for full 5 seconds. 1 = Drift; leg falls by the end of the 5-second period but does not hit bed. 2 = Some effort against gravity; leg falls to bed by 5 seconds, but has some effort against gravity. 3 = No effort against gravity; leg falls to bed immediately. 4 = No movement. UN = Amputation or joint fusion 6a. Left Leg 6b. Right Leg
7. Limb Ataxia: This item is aimed at finding evidence of a unilateral cerebellar lesion. Test with eyes open. In case of visual defect, ensure testing is done in intact visual field.	0 = Absent. 1 = Present in one limb. 2 = Present in two limbs. UN = Amputation or joint fusion
8. Sensory: Sensation or grimace to pinprick when tested, or withdrawal from noxious stimulus in the obtunded or aphasic patient. Only sensory loss attributed to stroke is scored as abnormal and the examiner should test as many body areas	0 = Normal; no sensory loss. 1 = Mild-to-moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched.

Contd...

Contd...

(arms [not hands], legs, trunk, face) as needed to accurately check for hemisensory loss.	2 = Severe to total sensory loss; patient is not aware of being touched in the face, arm, and leg.
9. Best Language: A great deal of information about comprehension will be obtained during the preceding sections of the examination. For this scale item, the patient is asked to describe what is happening in the attached picture, to name the items on the attached naming sheet and to read from the attached list of sentences	0 = No aphasia; normal. 1 = Mild-to-moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation on ideas expressed or form of expression. Reduction of speech and/or comprehension, however, makes conversation about provided materials difficult or impossible. For example, in conversation about provided materials, examiner can identify picture or naming card content from patient's response. 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by the listener. Range of information that can be exchanged is limited; listener carries burden of communication. Examiner cannot identify materials provided from patient response. 3 = Mute, global aphasia; no usable speech or auditory comprehension.
10. Dysarthria: If patient is thought to be normal, an adequate sample of speech must be obtained by asking patient to read or repeat words from the attached list.	0 = Normal. 1 = Mild-to-moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty. 2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to any dysphasia, or is mute/anarthric. UN = Intubated or other physical barrier,
11. Extinction and Inattention (formerly Neglect): Sufficient information to identify neglect may be obtained during the prior testing	0 = No abnormality. 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities. 2 = Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space.

Brott T et al.[168]

TABLE 133.29: The indications and contraindications for thrombolytic therapy in patients with acute ischemic stroke

Indications

- Ischemic stroke with symptom onset < 3 hours
- Measurable neurological deficit
  - Signs should not be clearing spontaneously
  - Signs should not be minor and isolated
  - Ideal candidates have NIHSS scores of 4–20 (estimation of risk/benefit ratio required)
  - Caution in patients with major deficits
- Patient and /or patient's designee/family comprehend potential risks and benefits of thrombolysis

Contraindications

- CT or MRI of brain demonstrates:
  - Intracranial hemorrhage
  - Hypodensity > one third of cerebral hemisphere
- Head trauma or stroke in the preceding 3 months
- Myocardial infarction in the preceding 3 months
- Gastrointestinal and urinary tract hemorrhage in last 21 days
- Arterial puncture at a non-compressible site in the last 7 days
- Major surgery in last 14 days
- Systolic blood pressure ≥ 185 mm Hg or diastolic blood pressure ≥ 110 mm Hg
- History of prior intracranial hemorrhage
- Evidence of active bleeding or acute trauma on physical examination
- Use of oral anticoagulation with INR > 1.7
- Use of heparin in last 48 hours with a prolonged aPTT level
- Platelet count ≥ 100 x 10^9/L
- Blood glucose level < 50 mg/dL
- Seizure with postictal residual neurological deficit

Abbreviations: NIHSS: National Institute of Health Stroke scale, CT: Computed Tomography, MRI: Magnetic Resonance Imaging, INR: International Normalized Ratio, aPTT: activated partial thromboplastin time.
Adapted from Adams et al.[166,170]

TABLE 133.30: The common and uncommon causes of spontaneous subarachnoid hemorrhage

Common	Cerebral aneurysms AVM
Uncommon	Neoplasms Dural AVM Venous angiomas Infectious aneurysms

xanthochromia which may persist for up to 2 weeks. A definitive diagnosis is made by angiography, which can identify the source of bleeding. Other tests which can be used are digital subtraction angiography or magnetic resonance angiography. The amount, location and extent of bleeding, correlates with prognosis.[178] A number of grading systems are used in practice to standardize the clinical classification of patients with SAH based upon the initial neurologic examination and the appearance of blood on the initial head CT.[179] They include the Glasgow Coma Scale (GCS) system, Hunt and Hess Grading System and The World Federation of Neurological Surgeons system.[180] The utility of these systems to predict prognosis is poor. Two of these grading systems are shown in Tables 133.32 and 133.33 respectively.

Management

The management of SAH is centered on three aspects which are delineated in detail in Table 133.34, namely:

- General management
- Definitive treatment (identifying and treating the causative lesion and preventing rebleeding)
- Treatment of complications.[180-185]

General management involves ICU monitoring, discontinuation of all antithrombotic medications and correction of any coagulopathy, if present. Blood pressure control is essential if elevated in these patients and may also be guided by monitoring of the patient's level of consciousness or intracranial pressure. The calcium channel blocker, nimodipine, has been shown to improve outcome in SAH patients, however the exact mechanism of this improvement is unknown and has been attributed

TABLE 133.31: The clinical symptoms and physical examination findings in subarachnoid hemorrhage (SAH)

Clinical history

Onset of headache: abrupt, maximal at onset, "thunderclap"

Severity: Very severe or worst of life

Associated signs and symptoms: Loss of consciousness, Diplopia, Seizure, focal neurological signs.

Physical findings

Finding	*Likely Location of aneurysm*
Diminished consciousness	Any
Nuchal rigidity	Any
Papilledema	Any
Retinal and subhyloid hemorrhage	Any
Third nerve palsy	Posterior communicating artery
Sixth nerve palsy	Posterior fossa
B/l weakness in legs or abulia	Anterior communicating artery
Nystagmus or ataxia	Posterior fossa
Aphasia, hemiparesis, left-sided visual neglect	Middle cerebral artery

TABLE 133.32: The Glasgow coma scale (GCS) which is scored between 3 and 15; 3 being the worst, and 15 the best. It is composed of three parameters: best eye response, best verbal response and best motor response. A score of 13 or higher is associated with mild brain injury; a score of 9 to 12 is associated with moderate injury; and a score of 8 or less represents severe brain injury

Eye opening	
Spontaneous	4
Response to verbal command	3
Response to pain	2
No eye opening	1
Best verbal response	
Oriented	5
Confused	4
Inappropriate words	3
Incomprehensible sounds	2
No verbal response	1
Best motor response	
Obeys commands	6
Localizing response to pain	5
Withdrawal response to pain	4
Flexion to pain	3
Extension to pain	2
No motor response	1

TABLE 133.33: The Hunt and Hess grading system for assessing the severity of sub-arachnoid hemorrhage

Grade	*Presentation*
1	Asymptomatic or mild headache and slight nuchal rigidity
2	Moderate to severe headache, stiff neck, no neurological deficit except cranial nerve palsy
3	Drowsy or confused, mild focal neurological deficit
4	Stupor, moderate or severe hemiparesis
5	Deep coma, decerebrate posturing

Mortality is minimum with grade 1 but maximum with grade 5.

TABLE 133.34: The steps involved in the management of sub-arachnoid hemorrhage

General management

- Admission to an intensive care unit
- Oxygen supplementation, mechanical ventilation if indicated
- Stool softeners, bed rest, analgesia to diminish hemodynamic fluctuations
- Correction of coagulopathy if any
- Control blood pressure
- Deep venous thrombosis (DVT) prophylaxis with pneumatic compression stockings; subcutaneous unfractionated heparin 5000 units three times daily can be added for prophylaxis, once the aneurysm is treated
- Monitor and treat elevated intracranial pressure
- Seizure prophylaxis

Identifying and treating the causative lesion and preventing rebleeding

- Team of experienced surgeons and endovascular practitioners
- To consider the neurologic grade and clinical status of the patient, the availability of expertise in surgical and endovascular techniques, the anatomic characteristics of the aneurysm, including the location and the size of the aneurysm and its neck
- Timing of surgery is controversial although early surgery is preferred
- Neurosurgical clipping is preferable over endovascular coiling

Treatment of complications

- **Treating hydrocephalus**
  Ventricular drain placement for deteriorating level of consciousness and no improvement in hydrocephalus within 24 hours
- **Treating and preventing vasospasm**
  Inflammatory reaction in the blood-vessel wall develops
  Between days 4 and 12 after subarachnoid hemorrhage
  Transcranial Doppler ultrasonography is performed either daily or every other day
  Treated with hypervolemia and induced hypertension
  May require treatment with temporary external ventricular drainage or the placement of a permanent shunt
- **Rebleeding**
  Manifests as worsening neurological state.
  Treat underlying cause.

to the prevention of vasospam.[186,187] The use of antiepileptic medication in SAH is controversial; therefore the routine use of antiepileptics is discouraged due to the poor neurologic outcome that has been reported with its use.[188] In addition, antifibrinolytic agents such as tranexamic acid and epsilon aminocaproic acid have been shown to decrease rebleed in SAH patients, but this is also without a significant effect on the general outcome of these patients.[189] This has been attributed to the development of generalized cerebral ischemia; hence these agents are not used routinely in SAH patients. The administration of glucocorticosteroids has also not been shown to be beneficial in these patients. The systemic factors contributing to the increased mortality include hypoxemia, metabolic acidosis, hyperglycemia and cardiovascular instability.[190]

TABLE 133.35: The complications of subarachnoid hemorrhage

Complication	*Features*
Hydrocephalus	May develop in 24 hrs due to obstruction to CSF flow by clotted blood
Seizures	Prophylaxis with anti-seizure medications
Raised intracranial pressure	Monitor closely
Re-bleeding	20% in 2 weeks with peak incidence on day 1 (4%) and 1.5% per day for 2 weeks
Vasospasm-	Arterial smooth muscle contraction
Neurological deficits	Cerebral ischemia
Hypothalamic dysfunction	Sympathetic stimulation leading to myocardial ischemia and labile blood pressure
Hyponatremia	SIADH
Pulmonary edema	Neurogenic and non-neurogenic causes
Complications from ICU stay	Identify and treat appropriately

Abbreviations: CSF: Cerebrospinal fluid, SIADH: Syndrome of inappropriate anti-diuretic hormone, ICU: Intensive care unit.

Definitive treatment involves either surgical clipping or endovascular coiling. There is a decreased mortality and a non-significant increase in rebleeding in patients treated with endovascular coiling as opposed to surgical clipping.[191] The timing of intervention is also controversial.

Complications of SAH are delineated in Table 133.35. Re-bleeding manifests with worsening neurological status and carries significant morbidity and mortality. The definitive therapy involves treatment of the aneurysm. Vasospasm starts approximately 3 days after the initial bleed and peaks after 7 to 8 days. It is associated with cerebral ischemia and neurological deficits, and the extent of vasospasm can be monitored using transcranial Dopplers. Irrigation of the cistern magna with urokinase following surgical or endovascular intervention has been shown to prevent vasospasm.[192] In addition, statins have also been shown to prevent vasospasm.[193] Triple H therapy (hemodilution, induced hypertension and hypervolemia) after definitive aneurysm treatment has been used in some centers to treat vasospasm. Furthermore, balloon angioplasty has been performed in patients with vasospasm that is refractory to triple H therapy.

Hydrocephalus is common in elderly patients with intraventricular bleeding, posterior circulation aneurysms and treatment with antifibrinolytic agents. Spontaneous resolution occurs in about 50% of cases. Hyponatremia can develop secondary to the Syndrome of Inappropriate Antidiuretic Hormone (SIADH) or with cerebral salt wasting. Clear distinction between these two entities is important for proper management: SIADH patients are euvolumic while cerebral salt wasting patients are hypovolemic.

Intracerebral Hemorrhage

Intracerebral hemorrhage (bleeding within the skull) occurs within the brain parenchyma or surrounding meningeal spaces. Brain hemorrhage can occur from defects in the vessel wall, such as aneurysms, arterio-venous malformations, small vessel microaneurysms, coagulopathy, increased blood pressure or trauma.[194-197] Intracerebral hemorrhage (ICH) accounts for 10 to 30% of all stroke hospital admissions and is associated with high mortality.[198] ICH can be classified into primary or secondary depending on the underlying cause of bleeding as delineated in Table 133.36. The causes of intracerebral hemorrhage are further outlined in Table 133.37. ICH commonly occurs in the cerebral lobes, cerebellum, basal ganglia, thalamus and brain stem with extension into ventricles with large hematomas. Cerebral edema and neuronal damage in the surrounding parenchyma also occurs. There are several mechanisms of brain injury in ICH:

- Primary direct mechanical injury to brain parenchyma by the expanding clot
- Increased intracranial pressure (ICP)
- Herniation secondary to mass effect

TABLE 133.36: The classification of intracerebral hemorrhage based on the cause of the bleeding

Primary intracerebral hemorrhage	• Accounts for majority of cases. • Caused by spontaneous rupture of small vessels damaged by chronic hypertension or amyloid angiopathy.
Secondary intracerebral hemorrhage	• Occurs in minority of patients. • Secondary to vascular abnormalities, tumors, and impaired coagulation.

TABLE 133.37: The various etiologies of intracerebral hemorrhage, with hypertension being the most common

- Hypertension
- Amyloid angiopathy
- Arteriovenous malformation
- Intracranial aneurysm
- Cavernous hemangioma
- Venous angioma
- Coagulopathy
- Vasculitis
- Intracranial neoplasm
- Hemorrhagic ischemic stroke
- Cocaine or alcohol usage

Clinical Features

The neurologic symptoms usually increase gradually over minutes to a few hours. Patients present with decreased level of consciousness as a result of increased ICP and direct compression of thalamic and brain stem Reticular Activating System (RAS). The majority of patients are hypertensive at time of presentation. Other symptoms include headache, seizures, vomiting which is more common with ICH than ischemic stroke. Stupor or coma in ICH is a warning sign with the exception of patients with thalamic hemorrhage, in whom involvement of the RAS is the cause of stupor rather than diffuse brain injury. These patients often recover after reabsorption of blood. Neurological signs vary depending on location of hemorrhage. In cases of severe intracerebral bleeding, herniation can take place. The clinical signs of the herniation syndromes are shown in Table 133.38.

Diagnosis

ICH is a neurologic and medical emergency as it is related with a high-risk of ongoing bleeding, progressive neurologic deterioration, permanent disability and death. Although rapid onset of abnormalities and decreased level of consciousness suggest the diagnosis, imaging with CT scan of brain is needed to confirm the diagnosis.[199] CT-scan of the brain is the initial diagnostic test and a cerebral angiography usually does not provide any further information, especially in elderly patients.[200] In addition to the CT-scan, patients should get CBC, coagulation profile and comprehensive metabolic panel. MRI can be useful in identifying large Arteriovenous Malformations (AVMs) and may be used in selected patients.[201]

TABLE 133.38: The herniation syndromes that can be seen with intracerebral bleeding

Type	*Causes*	*Clinical hallmark*
Lateral transtentorial (uncal)	Temporal lobe mass lesion	Ipsilateral CN 3 palsy Contralateral or bilateral motor posturing
Central transtentorial	Diffuse cerebral edema; hydrocephalus	Progression from bilateral decorticate to decerebrate posturing Rostral-caudal loss of brainstem reflexes
Subfalcine	Frontal or parietal mass lesion	Asymmetric motor posturing (contralateral > ipsilateral) Preserved oculocephalic reflex

Abbreviations: CN 3 – Third cranial nerve

Management

All patients with ICH should be monitored closely in the ICU.[202-205] Initial management of these patients includes evaluation of the airways, breathing and circulation (Table 133.39). Mechanical ventilatory support is usually recommended for patients with GCS of less than 8, but should be guided by the clinical presentation. The secondary effects of ICH include expansion of the hematoma, increased ICP, perihematomal edema, intraventricular hemorrhage and hydrocephalus. Treatment involves a combination of both medical and surgical interventions. Elevated blood pressure is common in patients with ICH and is feared to contribute to the expansion of hematoma.[206] Aggressive management of blood pressure to keep the mean arterial pressure (MAP) < 110 mmHg should be started immediately. The management of hypertension and hypotension is depicted in Table 133.40. Raised ICP contributes to the mortality of these patients and should be managed expediently. It is defined as a pressure more than 20 mmHg for >5 minutes. As soon as raised ICP is suspected, the head of the bed should be raised to 30° keeping the head at midline. Hypovolemia should be treated expediently to prevent postural hypotension.

TABLE 133.39: The steps involved in the management of intracerebral hemorrhage

1. **General management**
    - Reversal of anticoagulation
    - Treatment of fever source
    - Prevent and address hyperglycemia and hypoglycemia
    - Adequate treatment of pain
    - Seizure prophylaxis and treatment
    - DVT prophylaxis
    - Supplemental oxygen or intubation as indicated
2. **Intracranial pressure monitoring (ICP)**
    - Elevate head of bed
    - Hypovolemia should be treated
    - Ventriculostomy and CSF drainage for hydrocephalus
    - Osmotic therapy with mannitol, hypertonic saline
    - Sedation and paralysis as needed
    - Maintain ICP 5-20 (aggressive measures to decrease ICP)
    - Maintain cerebral perfusion pressure > 70 mm Hg
3. **Maintainence of optimum blood pressure**
    - MAP < 110 (some suggested medications are shown in Table 133.40)
4. **Address metabolic and nutritional needs**
    - Early administration of TPN worsens ICH
    - Start TPN after 2-3 days with high concentration of calories from lipids

Abbreviations: DVT: Deep vein thrombosis, CSF: Cerebrospinal fluid, MAP: Mean arterial pressure, TPN: Total parenteral nutrition, ICH: Intracerebral hemorrhage.

TABLE 133.40: The management of hypotension and hypertension in acute intracerebral hemorrhage

High blood pressure	
1. If SBP is >200 mm Hg, or MAP >150 mm Hg on 2 readings 20 minutes apart	Start intravenous labetalol, esmolol, enalapril, or other smaller doses of easily titratable intravenous medications such as diltiazem, lisinopril, or verapamil
2. If SBP is >180 mm Hg and MAP <130 mm Hg with elevated ICP.	Start intravenous antihypertensives (Agents shown below)
3. If SBP is >180 mm Hg and MAP <130 mm Hg with no elevation of ICP	Intermittent or continuous antihypertensives can be used. The goal is to keep SBP< 160 mmHg and MAP ~ 110 mm Hg
Labetalol	5–100 mg/h by intermittent bolus doses of 10–40 mg or continuous drip (2–8 mg/min)
Esmolol	500 µg/kg as a load; maintenance → 50–200 $\mu g \cdot kg^{-1} \cdot min^{-1}$
Nitroprusside	0.5–10 $\mu g \cdot kg^{-1} \cdot min^{-1}$
Hydralazine	10–20 mg every 4–6 h
Enalapril	0.625–1.2 mg every 6 h as needed
Low blood pressure	
Volume replenishment is the first line of approach. If hypotension persists after correction of volume deficit, continuous infusions of pressure should be considered, particularly for low systolic blood pressure such as < 90 mm Hg.	
Phenylephrine	2–10 $\mu g \cdot kg^{-1} \cdot min^{-1}$
Dopamine	2–20 $\mu g \cdot kg^{-1} \cdot min^{-1}$
Norepinephrine	Titrate from 0.05–0.2 $\mu g.kg^{-1}$. min^{-1}

Abbreviations: SBP: Systolic blood pressure, MAP: Mean arterial pressure, ICP: Intracranial pressure.

Osmotic therapy with mannitol decreases the swelling of an edematous brain, decreases the viscosity of blood and increases cardiac preload thus increasing the Cerebral Perfusion Pressure (CPP). The target osmolality is 310 to 320 osmols. Mannitol is given in a dose of 0.5 to 1 g/kg every 4 to 6 hours. Side effects include volume overload and osmotic renal failure. The effect of mannitol is seen within 30 minutes to 1 hour and is guided by clinical improvement. Hypertonic saline, either as a 3% saline 150 mL bolus every 6 hours or as a continuous infusion of 0.5 ml to 1 ml/kg/hr, is also recommended for the treatment of raised ICP. Frequent serum sodium moni-toring is required with hypertonic saline administration. Alternatively, 7.5% saline as a 250 mL bolus or 23.4% saline in doses of 30 to 60 mL over 20 minutes can be used when other modalities are unsuccessful. Sudden increases in sodium can contribute to the development of coma and seizures. Steroids are not recommended for cerebral edema secondary to CVA.

Hyperventilation has an immediate and transient effect on cerebral circulation. It lowers CPP by cerebral vasoconstriction and may be associated with exacerbations of ischemia in local regions of the brain. It is recommended to lower the $PaCO_2$ to 30 to 35 mmHg in situations of an intractable rise in CPP.[207] Hyperthermia worsens neurological damage by increasing the metabolism in ischemic brain tissues. Therapeutic cooling to a temperature of 30° to 32° C and gradual rewarming may improve outcomes.[208] The role of ventriculostomy and CSF drainage has not been studied prospectively, but is an effective method of decreasing ICP, especially in the phase of hydrocephalus.[209] Inter-ventricular hemorrhage and infection are notable complications of this procedure.[210]

In addition to these specific treatments, patients should be treated adequately for pain. Sedation and neuromuscular blockade may be needed for patients who are intubated. Also, blood glucose should be lowered to less than 150 mg/dL, but hypoglycemia should be avoided.[211] Since most of the seizures are nonconvulsive in nature, prophylactic seizure medications must be used initially.[212]

Patients with ICH have a high incidence of venous thromboembolism and should receive prophylaxis initially with pneumatic compression stockings and later subcutaneous heparin 5000 units every 8 hours after day 4 of ICH onset.[213] Patient who developed venous thromboembolism should be treated with an Inferior Venacaval (IVC) filter.[214] Warfarin treatment increases the incidence of ICH and the risk is proportional to the degree of anticoagulation and the presence of amyloid vasculopathy. The anticoagulant effect is rapidly reversed using Vitamin K 10 mg intravenously, Fresh Frozen Plasma (FFP), prothrombin complex concentrate and recombinant factor 7a (rFVIIa).[215] The reinstitution of warfarin therapy should be carefully assessed on an individual basis. ICH associated with antifibrinolytic therapy carries a worse prognosis than warfarin associated ICH and is treated with platelets and cryoprecipitate.[170]

Surgical treatment is not beneficial except in certain selected conditions.[216] The stroke association recommendations for surgery are as follows:

1. Cerebellar hematoma > 3 cm especially with neurological deterioration, brainstem compression or hydrocephalus should be removed as soon as possible
2. Patient with lobar clots within 1 cm of the surface of the brain, evacuation of supratentorial ICH by standard craniotomy may be considered
3. The usefulness of urokinase infusion into the clot or minimally invasive evacuation of the clot or routine decompressive craniotomy is currently unknown.[203] In one small study, decompressive craniotomy had a better outcome in young patients.[217]

Prognosis

A simple six-point clinical grading scale called the ICH score has been devised to predict mortality after ICH.[218] This scale incorporates several clinical components that may be independent predictors of outcome. The ICH score is determined by adding the score from each component (Table 133.41).

TABLE 133.41: The six-point ICH scoring used to predict mortality after the development of ICH. A cumulative ICH score is obtained by adding the points from each component

Scale	*Points*
GCS score	
3-4	2
5-12	1
13-15	0
ICH volume	
≥ 30 cm^3	1
≤ 30 cm^3	0
Intraventricular extension of hemorrhage	
Present	1
Absent	0
Infratentorial origin	
Yes	1
No	0
Age	
≥ 80 years	1
< 80 years	0

Abbreviations: ICH: Intracerebral hemorrhage, GCS: Glasgow coma scale.

Status Epilepticus

Seizures are a common condition seen in 3.3 to 34% of ICU patients.[219] They can result from either a primary neurological pathology such as a stroke, brain tumor or Central Nervous System (CNS) infection, or develop as a neurological complication of critical illness as in patients with metabolic abnormalities, drug/substance toxicity or withdrawal, or hypoxemia.[219,220] Status epilepticus is said to occur when seizures are recurrent or refractory lasting more than 5 minutes or repetitive in nature without regaining consciousness in between episodes.[219,221] It is a life-threatening emergency that necessitates urgent diagnosis and treatment, and is classified as either being convulsive or nonconvulsive. The convulsive form tends to be the more severe and common type, and is characterized by repeated seizure episodes associated with a postictal state, while the nonconvulsive form is characterized typically by an altered mental status and a lack of obvious physical manifestations.[220,222] Common causes of status epilepticus are outlined in Table 133.42.

Clinical Features and Diagnosis

Patients with convulsive status epilepticus are easy to recognize as they present with classic motor manifestations. Conversely, patients with nonconvulsive status epilepticus often go unrecognized because of the lack of obvious signs. The use of Electroencephalography (EEG) is therefore an essential tool in the diagnosis of the nonconvulsive type. The basic diagnostic work up also includes a rapid assessment of glucose levels, CBC, electrolytes, liver function, arterial blood gas analysis, toxicology screen, in addition to imaging studies like CT-scan or MRI of the brain. A lumbar puncture may also be performed in selected patients to evaluate the CSF for possible secondary causes of the seizure episodes. The prompt diagnosis and treatment of status epilepticus is essential, as prolonged or recurrent seizure episodes are associated with worsening neurological injury and systemic complications such as lactic acidosis, hyperthermia, arrhythmias, aspiration, rhabdomyolysis, renal failure and trauma.[220]

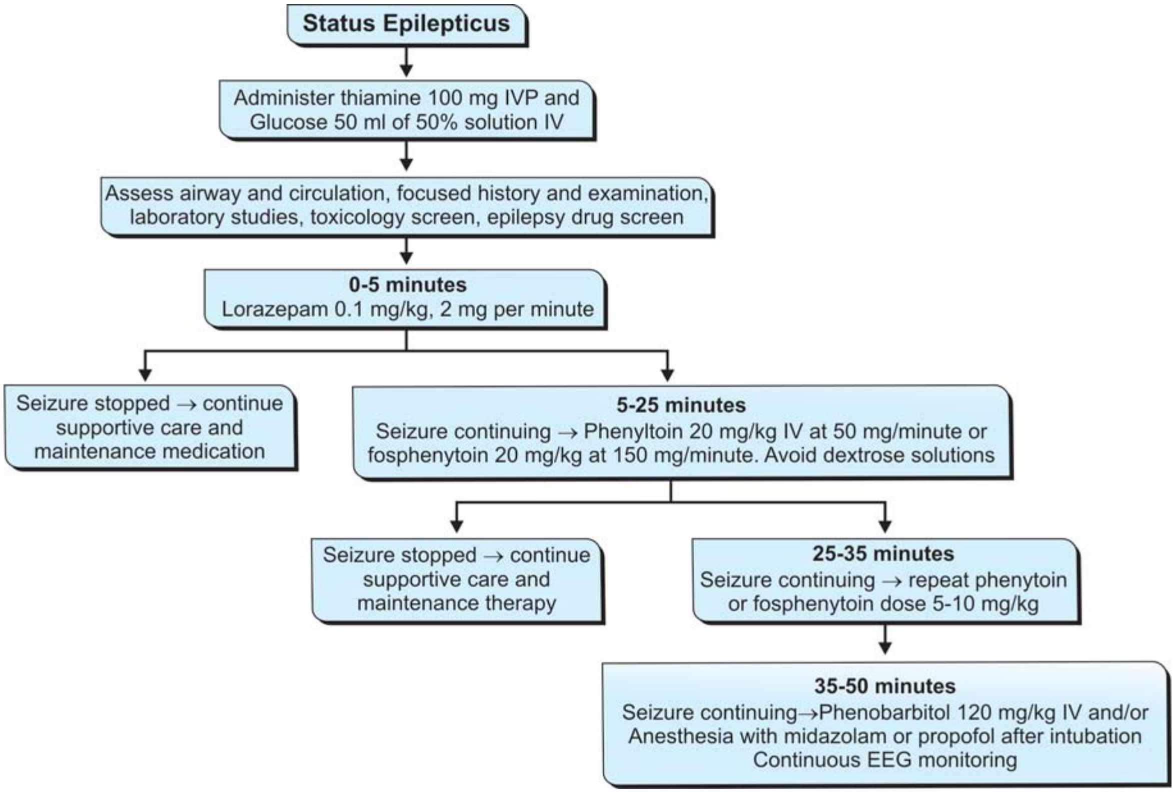
TABLE 133.42: The different etiologies associated with the development of status epilepticus

- Antiepileptic drug noncompliance
- Alcohol related
- Cerebrovascular accidents
- Vascular malformations
- Drug toxicity
  (Cephalosporins, penicillins, ciprofloxacin, tacrolimus, cyclosporin, theophylline and cocaine)
- CNS infections (Meningitis, encephalitis, abscess)
- CNS tumors (Primary or secondary)
- Metabolic disturbances
  (Electrolyte abnormalities, sepsis and uremia)
- Head trauma
  Surgery
- Cerebral anoxia/hypoxia
- Hypoglycemia or hyperglycemia
- Vasculitis

Abbreviation: CNS: Central nervous system.

Management

The EEG not only serves as a diagnostic tool, but also aids in monitoring response to treatment, as patients may still be actively seizing even though motor signs have subsided. Treatment involves eliminating seizure activity as well as preventing the development of further episodes.[220] The general and pharmacological strategies employed in the management of status epilepticus are shown in Figure 133.7.[221] The initial step in treatment involves evaluating the respiratory and cardiovascular status of the patient. Patients are frequently intubated in order to preserve the airway and enhance oxygenation.[219] A rapid blood glucose test is usually performed at bedside and treated for levels < 60 mg/dL and at the same time blood is sent off for blood tests as listed earlier.[219,220] Benzodiazepines are the initial drug of choice. Intravenous lorazepam 1 to 2 mg, midazolam 2 to 5 mg or diazepam 10 to 20 mg can be given at first but these doses can be increased up to 5 to 10 mg, 5 to 20 mg or 20 to 40 mg over 5 minutes in cases of recurrent or refractory seizures.[219] In patients not responding to the increased doses of benzodiazepines, second line agents that have been used include phenytoin (loading dose 20 mg/kg at 50 mg/minute) or fosphenytoin (20 mg/kg at 150 mg/minute).[219,220] Other alternative second line agents that can be used include intravenous medications like levetiracetam and valproic acid.[223,224] In patients who still continue to have seizure episodes (> 60 minutes), induction of a pharmacological coma may be necessary with infusions of phenobarbital, propofol or midal-zolam.[219,225-227] Continuous EEG monitoring is also preferred, particularly in patients with nonconvulsive status epilepticus. Status epilepticus is a serious condition in critically ill patients and is associated with a mortality



Status Epilepticus
Administer thiamine 100 mg IVP and Glucose 50 ml of 50% solution IV
Assess airway and circulation, focused history and examination, laboratory studies, toxicology screen, epilepsy drug screen
0-5 minutes
Lorazepam 0.1 mg/kg, 2 mg per minute
Seizure stopped → continue supportive care and maintenance medication
5-25 minutes
Seizure continuing → Phenyltoin 20 mg/kg IV at 50 mg/minute or fosphenytoin 20 mg/kg at 150 mg/minute. Avoid dextrose solutions
Seizure stopped → continue supportive care and maintenance therapy
25-35 minutes
Seizure continuing → repeat phenytoin or fosphenytoin dose 5-10 mg/kg
35-50 minutes
Seizure continuing→Phenobarbitol 120 mg/kg IV and/or Anesthesia with midazolam or propofol after intubation
Continuous EEG monitoring

Fig. 133.7: An algorithmic approach to the management of status epilepticus.
Abbreviations: IVP – Intravenous push, IV – Intravenous, EEG – Electroencephalogram

of approximately 20%.[228] Early recognition and treatment is necessary to prevent the potentially severe neurological consequences.

Poisoning, Envenomation and Environmental Injuries

Dhruva Chaudhry, Inder Pal Singh, Deepak Govil

INTRODUCTION

A large number of patients admitted in the hospitals for nonpulmonary problems, such as poisonings, snake envenomation, trauma, environmental injuries or with tropical infections like malaria, leptospirosis, tetanus and others with or without the involvement of lungs or respiratory muscles or both need intensive respiratory care where life is seriously threatened. In our own multidisciplinary Intensive Care Unit (ICU), 72% of 459 admissions in 2009 were due to the nonpulmonary causes of critical illnesses with 23% due to poisoning and neuroparalytic snake envenomation, 11% due to primary neurological conditions and 38% due to tropical infections (malaria, typhus, etc.), polytrauma, endocrinological emergencies, obstetrical and postsurgical critical illness.

POISONING

Acute poisoning is an important medical emergency needing admission in critical care units. Poisoning is an event where a living organism is exposed to a chemical that adversely affects the functioning of that organism.[1] The exposure to the toxin, which could be occupational, environmental, recreational or medicinal can occur through various portals of entry, but predominantly the oral route. A poison may affect the body in many different ways. It may inhibit, or alter the normal cellular function, change normal organ function, or may change the normal uptake or transport of substances into or within the organism.[2]

The nature of poisons which are used varies in different parts of the world and even in different parts of the same country depending on the socioeconomic factors and cultural diversities.[3] Self-poisoning, including of pesticides accounts for about one-third of the world's suicides. Official data from India probably underestimate the incidence of suicides.[4] The proportion of all suicides using pesticides varies from 4% in the European region to over 50% in the Western Pacific region. It is the pattern of pesticide use and the toxicity of the product, not the quantity used, that influences the likelihood that they will be used in the acts of fatal self-harm.[5] In general, accidental poisoning is more common in children, whereas suicidal poisoning is more so in young adults.[6,7]

It is important for the intensivists to know the pattern of poisoning in their area. Across India, pesticides (organophosphates and organochlorine) and fumicide (aluminium phosphide) are the common poisons used for self-harm in rural and semi-urban areas, whereas household products and drugs are commoner in the metropolitan/city areas.[8] Epidemiological studies demonstrating the patterns of poisoning in critical care are scanty. It is believed that the major share of poisoning in critical care units is contributed by pesticides and fumicides across the country since they cause most of the cases of severe intoxication[6-9] and deaths due to poisoning.[10]

Toxic ingestion presents variably. Patients often arrive with known drug overdose or toxic exposure, such as in the setting of illicit drug use, suicidal attempt or accidental exposure. In others, history is unclear, particularly when there is associated trauma or alterations in mental status. Clinical features may be specific for a toxic syndrome (or toxidrome), but just as often nonspecific and suggestive of other disorders.

The protean manifestations of intoxication mandate a higher index of suspicion to facilitate decisive and immediate treatment. General supportive measures supersede all other considerations. For the effective management of acutely poisoned victim the following should be considered:

I. Resuscitation and stabilization.
II. Diagnosis of poisoning and drug overdose (history, physical examination, use of toxicological screening tests, including other common laboratory tests).
III. Treatment and prevention of further drug absorption, elimination of absorbed drugs and antidotes.
IV. Specific approaches for evaluation and treatment of commonly encountered drugs, toxins and envenomations in the intensive care unit.

Resuscitation and Stabilization

The initial step is to identify and treat immediate life-threatening problems, which revolves around the pneumonic A B C D (Airway; Breathing; Circulation; Drugs and Decontamination).

Airway

With cervical precautions in place, airway patency and stabilization must be established. In comatose patients, upper airway obstruction by the tongue may be treated initially with jaw thrust maneuver, followed by the either placement of oral or nasal airway or an endotracheal tube. The choice of airway depends upon the level of sensorium, vigor of protective reflexes, degree of respiratory depression, and the initial response to the pharmacological therapy. In the nonintubated patients, the left side down, head-down position allows the tongue to drop forwards and decreases the risk of aspiration of oral secretions and stomach contents.

Breathing

It includes the maintenance of adequate oxygenation and ventilation. In the case of doubt regarding patient's ability to handle secretion or the maintenance of spontaneous respiration, endotracheal intubation should be done immediately. Intubation allows for the administration of high concentration of supplemental oxygen in hypoxemic patients and for assisted ventilation in patients with ventilatory failure.

Hypoxemia should be corrected immediately to avoid anoxic damage to brain, myocardial ischemia and cardiac arrhythmias. If the intubation is done solely for airway protection or to provide supplemental oxygen, then it must be connected to a T-piece. For patients with ventilatory failure, ventilation is achieved by mechanical ventilation. The initial settings of the ventilator are as per the clinicians comfort and the one which achieves greatest degree of synchrony between the patient and the machine. The initial ventilator mode should provide adequate backup minute ventilation.

Circulation

After ensuring adequate airway patency, oxygenation and ventilation, circulatory status of the patient should be assessed. Circulatory manifestation of poisoning can range from hypotension, hypertension, bradycardia, tachycardia to cardiac arrest.

Drugs and Decontamination

Give an antidote when there is reasonable certainty of a specific diagnosis. The indications and dosages are discussed subsequently. Decontamination consists of skin, eyes and gastrointestinal decontamination and facilitation for increased drug removal.

Decontamination of skin: Decontamination means separation of patient from the contaminant, i.e. poison in this instance. Many toxins, such as organophosphates and organochlorines are readily absorbed through the skin, systemic absorption can be prevented only by rapid action.

Wash the affected areas with the copious amounts of lukewarm water or saline. Wash carefully behind the ears, under the nails, and the skin folds. For oily substances (pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (alcohol) are rarely indicated and in some cases may paradoxically enhance the absorption.

Gastrointestinal decontamination:[11,12] Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective clinical trials have failed to show improved outcomes after gastric emptying. For small and moderate ingestion of most substances, oral-activated charcoal alone without prior gastric emptying is recommended. Exceptions are the large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is **not recommended** for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. It is also contraindicated in stuporous or comatose patients with absent gag reflexes unless their airway is secured beforehand.

Increased drug removal: Different ways of increased drug removal includes:

i. *Urinary manipulation:* Renal excretion can become a major route of excretion under conditions of forced diuresis. Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) outweighs its benefits, and is usually not recommended. It is used commonly in the toxicity of acidic drugs (e.g. salicylates, phenobarbital) as they are more rapidly excreted with alkaline urine. Urinary alkalinization is usually achieved by the administration of intravenous sodium bicarbonate (1 to 2 mEq/kg every three to four hours); this may be administered as two 50 ml ampoules of 8.4% sodium bicarbonate (each containing 50 mEq of $NaHCO_3$) per liter of 5% dextrose in water infused at 250 ml/hour with aim to keep urinary pH above seven.[13] Complications of this therapy include alkalemia (particularly in the presence of respiratory alkalosis), volume overload, hypernatremia and hypokalemia. It is particularly important to avoid hypokalemia, which prevents the excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. Addition of potassium chloride to the bicarbonate infusion is commonly required and is used prophylactically to prevent this complication.[14]

ii. *Hemodialysis:* The indications for hemodialysis are as follows: (a) Known or suspected potentially lethal amounts of dialyzable drug (Table 134.1), (b) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures, (c) Poisoning in patients with severe kidney, cardiac, pulmonary or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy is of uncertain benefit for the elimination of most poisons, but has been used successfully in the management of lithium poisoning.[15]

iii. *Repeat dose charcoal:* Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3-4 hours, may hasten the elimination of some drugs (phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (gut dialysis). However, clinical studies have failed to prove better outcome using multiple dose charcoal.[15,16]

TABLE 134.1: Drugs which can be removed by hemodialysis

Poison	*Indication*
Carbamazepine	Seizures, severe cardiotoxicity; serum levels > 60 mg/l
Ethylene glycol	Acidosis, serum level > 50 mg/dl
Lithium	Severe symptoms; level > 4 mEq/l more than 12 hours after last dose
Methanol	Acidosis, serum levels > 50 mg/dl
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, Level > 100 mg/dl (acute overdose) or > 60 mg/dl (chronic intoxication)
Theophyllines	Serum level > 90-100 mg/l (acute) or seizures and serum level > 60 mg/l (chronic)
Valproic acid	Serum level > 900-100 mg/l or deep coma, severe acidosis.

Diagnosis of Poisoning

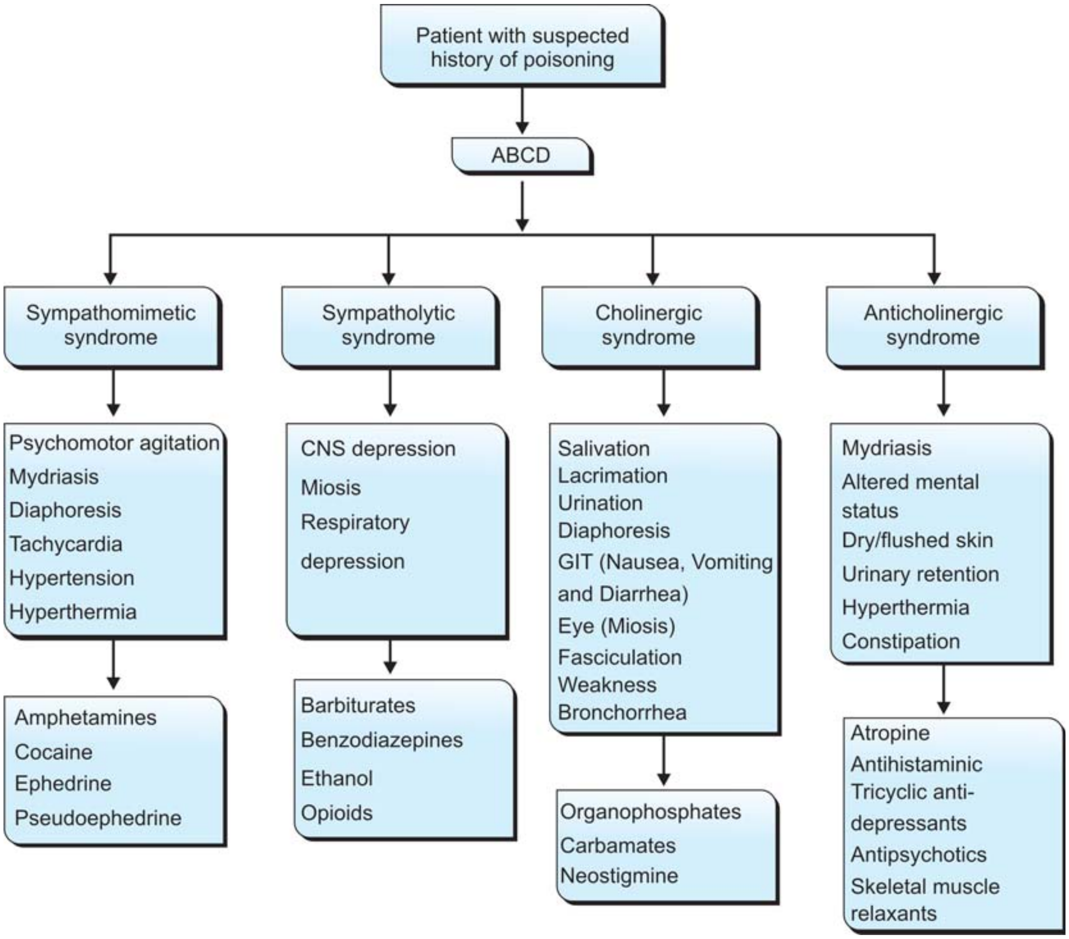
Because of its protean manifestations, poisoning and drug overdose should be considered in the differential diagnosis of all patients in an acute care setting. The identity of the ingested substance is usually unknown. The history is the single most important indicator of toxic ingestion, but for in a comatose patient or if the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis, which allows for the management of the patient (Fig. 134.1).

Treatment of Symptomatic Patient

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Every effort should be made to keep the patient alive. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in acute care facility. The following complications may occur, depending upon the type of poisoning.

Coma

Coma is commonly associated with the ingestion of the large number of drugs and toxins (Table 134.2). The most common cause of death in a comatose patient is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are obtunded or having seizures. Thus, the protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient in coma.



Patient with suspected history of poisoning
ABCD
Sympathomimetic syndrome
Sympatholytic syndrome

Fig. 134.1: Toxidromic approach to the diagnosis of poisoning
(ABCD = Airway maintenance, Breathing, Circulation, Drugs and Decontamination)

TABLE 134.2: Common causes of coma due to an exogenous agent

Hypoxia
Carbon monoxide

Depression of CNS
Alcohol, benzodiazepines, antidepressants, antihistamines, barbiturates, opiates, anticonvulsants

Acidosis
Ethylene glycol, alcohol, methanol, salicylates

Hypoglycemic agents
Alcohol, exogenous insulin, oral hypoglycemic agents (sulfonylureas)

Enzyme inhibitors
Heavy metals (arsenic, lead, etc.), organophosphates, salicylates, cyanide

Post ictal
Amphetamines, cocaine, hallucinogens, opiates, organochlorines, lead, phenothiazines, drug withdrawl

Other causes
Snake bites

Treatment: The initial emergency management of coma is on the lines of A B C. Immediately after stabilizing, a "coma cocktail" of thiamine, dextrose and naloxone should be administered. All comatose or convulsing patients should receive 50–100 ml of 50% dextrose. In alcoholic or severely malnourished patients, 100 mg of thiamine intravenously over 2–3 minutes should be administered prior to glucose. Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically in all coma patients. If however, opioid poisoning is strongly suspected, the additional dose of 5 to 10 mg may be required to reverse the effects. Flumazenil, 0.2–0.5 mg intravenously repeated every 30 seconds or as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma.

Agitated or Convulsing Patient

Agitated, violent or acutely psychotic patients unresponsive to verbal feedback and reduction in environmental stimuli require pharmacological treatment or physical restraints to establish patient safety. Organic causes of agitation other than drug overdose should be considered like drug withdrawal, head trauma with subdural hematoma, intracerebral hemorrhage, hypoglycemia, etc.

Seizures are a major cause of drug-related morbidity and mortality. They are caused by multiple drugs and toxins (Table 134.3). Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia and rhabdomyolysis and hence require early active intervention.

Treatment: In an agitated patient haloperidol (1 to 5 mg) may be repeated every 30 to 60 minutes to a total dosage not exceeding 100 mg. Haloperidol lowers seizure threshold and is associated with tardive dyskinesia. For seizures, administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 2 to 3 minutes. If seizures are not controlled consider phenobarbitone, 15–20 mg/kg slowly over no less than 30 minutes; or phenytoin 15 mg/kg intravenously not exceeding 50 mg per minute. For drug-induced seizures phenobarbitone is generally preferred over phenytoin. Propofol infusion has also been reported effective for some resistant drug-induced seizures.[17]

TABLE 134.3: Common compounds causing seizures

- Amphetamines
- Antihistamines
- Antipsychotics
- Carbamates
- Organochlorines
- Carbon monoxide
- Cocaine
- Ethylene glycol
- Cyclic antidepressants
- Isoniazid
- Salicylates
- Withdrawal from alcohol or sedative-hypnotics
- Organophosphates

In patients with seizures, the absence of visible muscular convulsive movements may give a false impression that brain seizure activity has ceased; however, this must be confirmed by electroencephalogram, wherever possible.

Temperature Alteration

Many drugs and toxins have the potential to alter body temperature through a number of different mechanisms. Both hypothermia and hyperthermia are common with intoxication. Hypothermia is caused by peripheral vasodilatation, inhibition of shivering, depression of metabolic activity, and loss of consciousness in cold environment. Hyperthermia occurs due to excessive generation of heat from sustained seizures, muscle rigidity, increased metabolic rate as in cocaine intoxication, or due to impaired dispersion of heat secondary to decreased sweating as in anticholinergic ingestion. Hyperthermia can also occur due to central causes that alter hypothalamic activity.

Treatment: Significantly abnormal temperature must be identified immediately and treated aggressively to prevent life-threatening complications. For hypothermic patient, gradual rewarming is preferred except in case of cardiac arrest. Hyperthermia should be managed aggressively by removing all clothes, spraying with tepid water and fanning the patient. If this is not rapidly effective, as shown by normal rectal temperature within 30–60 minutes or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated. Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (i.e. malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has also been recommended for neuroleptic syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, has been used to treat serotonin syndrome.[18]

Circulatory Manifestation

Circulatory manifestations of drug overdose are common and varied, including cardiac arrest, atrial and ventricular arrhythmias, and hypotension and hypertension (Table 134.4).

Treatment: Hypertension should be treated if the patient is symptomatic or if diastolic blood pressure is greater than 105-110 mm Hg especially if there is no prior history of hypertension. Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2-3 mg intravenously. For persistent hypertension, administer phentolamine, 2-5 mg intravenously, or nitroprusside sodium, 0.25-8 mcg/kg/min intravenously. Beta-blockers should not be given alone that may paradoxically worsen hypertension as a result of unopposed alpha-adrenergic stimulation.[19]

For hypotension, most patients respond to empiric treatment with repeated 200 ml intravenous boluses of 0.9% saline or other isotonic crystalloid (up to a total of 1-2 liter). **If fluid therapy** is not successful, dopamine at a dose of 5–15 mcg/kg/min by intravenous infusion may be given. Pulmonary artery catheterization may be done if hypotension persists. Hypotension due to certain drugs may need specific treatment. For example, in tricyclic antidepressant poisoning sodium bicarbonate (50–100 mEq by intravenous bolus injection) reverses hypotension; norepinephrine (4–8 mcg/min) is more effective then dopamine; for beta-blockers, glucagon (5–10 mg intravenously) may be more value; for calcium channel blocker overdose, calcium chloride at a dose of 1–2 g intravenously (repeated doses) may be administered. Intralipid 20% lipid emulsion has been reported to improve hemodynamics in intoxication by highly lipid soluble drugs, such as bupivacaine, verapamil, bupropion and clomipramine.[20]

TABLE 134.4: Factors associated with hypotension and hypertension

Hypertension and tachycardia	Amphetamines, cocaine, phencyclidine
Hypotension with bradycardia	Phenelzine, monoamine oxidase inhibitors, levodopa, organophosphates, tricyclic antidepressants
Hypertension with normal or slowed pulse	Phenylpropanolamine
Malignant hypertension with intracranial hypertension	Amphetamine, cocaine, phencyclidine, phenylpropanolamine
Hypotension and tachycardia	Theophyllines, cyanide, carbon monoxide, aluminium phosphide
Tachycardia with little change in blood pressure	Lomotil, Marijuana, thyroxine
Muscarinic syndrome	Organophosphates, pilocarpine, bethanechol

Arrhythmias are often caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmics doses. Class 1a agents should be avoided as they may worsen tricyclic antidepressant intoxication. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing.[21]

Pupil Size

Pupil size can be of help in diagnosis of intoxications (Table 134.5).

TABLE 134.5: Drugs causing pupillary alterations

Miosis	*Mydriasis*	*Nystagmus*
Narcotics	Deep coma	Barbiturate
Phenothiazine	Alcohol	Phenytoin
Barbiturate	Atropine	Phencyclidine
Organophosphates	Anticholinergics	Alcohol
	Glutethimide	
	Diphenhydramine	
	Cocaine	

Laboratory Evaluation

Clinical laboratory data includes the assessment of three "gaps" of toxicology: the anion gap, the osmolal gap, and the arterial oxygen saturation gap.

a. *Anion gap:* Metabolic acidosis associated with an elevated anion gap is usually due to the accumulation of lactic acid or other acids. There are various causes of disturbed anion gap (Table 134.6). It is measured by:

$$[AG = Na^+] - [Cl^-] - [HCO_3^-]$$

The normal value is 12±4 mEq/L.

b. *Osmolal gap:* Certain drugs and toxins of low molecular weight produce discrepancy between measured and calculated plasma osmolality.[22] Osmolality is calculated by:

Calculated osmolality =
$2\,[Na^+] + [BUN]/2.8 + [glucose]/18 + [ethanol]/4.6.$

TABLE 134.6: Drugs associated with anion gap disturbance

Increased anion gap
- Carbon monoxide
- Cyanide
- Ethanol*
- Ethylene glycol*
- Formaldehyde
- Methanol*
- Salicylates

Decreased anion gap
- Hyperkalemia
- Hypercalcemia
- Acute lithium intoxication
- Bromide
- Hypermagnesemia

*Also have an increased Osmolal gap

Methanol and ethylene glycol are unique in producing both severe metabolic acidosis with elevated anion gap and an elevated osmolal gap (Table 134.6).

c. *Oxygen saturation gap:* Carbon monoxide and methemoglobin are associated with an elevated arterial oxygen gap (> 5% difference of the calculated from the arterial blood gas determination and saturation measured by co-oximetry). These toxins interfere with the oxygen binding to hemoglobin and thereby significantly decrease oxygen content without lowering PaO_2. Oxygen saturation measured by pulse oximetry is falsely high in the setting of these toxins.

d. *Toxicology screening:* Toxicology screening provides the direct evidence of ingestion, but it rarely impacts initial management, and initial supportive measures should never await the results of such analysis. If toxicology screen is required, urine is the best specimen (Table 134.7). Quantitative blood analysis of suspected drugs can be useful for diagnostic and therapeutic reasons, particularly in overdoses involving alcohols, acetaminophen, salicylates, and cyclic antidepressants.

Treatment of Specific Intoxications

Certain drugs or toxins can be managed by specific antidotes (Table 134.8).

Acetaminophen

Acetaminophen is the most popular "available over-the-counter" analgesic. It is the commonest poisoning in the western world especially in UK. However, it is uncommon in Indian subcontinent and other developing world. The toxic dose is > 150–200 mg/kg, or 8–10 grams in an average adult. Acetaminophen is primarily metabolized by liver through sulfation (20 to 46%) and glucuronidation (40 to 67%). A small percentage is oxidized to a toxic metabolite, N-acetyl-p-benzoquinoneimine (NAPQ1), by cytochrome P-450, which is quickly detoxified by the hepatic stores of glutathione to a nontoxic acetaminophen–mercaptate compound that can be eliminated through renal excretion. During toxic overdose a larger proportion is metabolized by cytochrome P-450 to NAPQ1, depleting glutathione.[23]

Clinical features: The evolution of acetaminophen toxicity is divided into four phases:[24,25]

TABLE 134.7: Drugs detected in urine

Drugs detected within 30 minutes
- Amphetamines
- Barbiturates
- Benzodiazepines
- Cocaine
- Opioids
- Phencyclidine

Drugs detected within 2-3 hours
- Acetaminophen
- Cannabinoids
- Phenothiazine
- Morphine
- Propranolol
- Ephedrine

TABLE 134.8: Specific antidotes for drugs and toxins

Drug/poison	*Antidote*
Acetaminophen	N-acetylcysteine
Anticholinergics	Physostigmine
Anticholinesterases	Atropine
Benzodiazepines	Flumazenil
Beta-blockers	Glucagon
Calcium channel blocker	Calcium chloride, glucagon
Cyanide	Amyl-nitrite, sodium nitrite, sodium thiosulfate
Digoxin	Digoxin specific antibodies
Ethylene glycol	Ethanol
Heavy metals	Dimercaprol(bal), edta, penicillamine
Opioids	Naloxone
Hypoglycemic agents	Dextrose, glucagon

Phase I refers to the first 24 hours after ingestion. Patients generally remain alert, but may experience nausea, vomiting, anorexia, malaise, pallor or diaphoresis.

Phase II occurs 24 to 72 hours after untreated ingestion. During this period, patient may develop the right upper quadrant pain and minor abnormalities of the liver function consisting of elevation of hepatic enzymes, prothrombin time and bilirubin.[26]

Phase III (72 to 96 hours after untreated ingestion) is characterized by continued hepatic necrosis, hepatic encephalopathy, disseminated intravascular coagulation and jaundice. Liver function abnormalities typically peak during phase III. The liver enzymes may rise to 10,000 IU/L or higher. Rare phase III sequel include hemorrhagic pancreatitis, renal failure and myocardial necrosis.[26]

Phase IV occurs four days to two weeks after ingestion, during which recovery occurs, with the return of enzymes to the normal range and without the development of chronic liver damage.

In some patients, there is a rising trend of prothrombin time, ammonia and bilirubin even though the levels of hepatic enzyme decline indicating fulminant hepatic failure.

Diagnosis: The diagnosis of acetaminophen toxicity depends upon serum levels and the time elapsed after ingestion. The interpretation of acetaminophen toxicity depends up on plotting of Rumack-Matthew nomogram.[26] The nomogram applies to an acetaminophen level measured after four hours following ingestion and before 24 hours after ingestion. Patients with four hours level of 200 µg/ml nomogram have a 60% risk of developing hepatotoxicity and a 5% risk of death.[27] Patients with four hour levels of 300 µg/ml have a 90% risk of developing hepatotoxicity.[28]

Treatment: Charcoal should be given within one to two hours of ingestion. One must treat if the serum acetaminophen level is above the nomogram line, i.e. four hour level of ≥ 200 µg/ml. If the precise time of ingestion is unknown, then a lower threshold of 100 µg/ml at four hours may be taken for treatment. Treatment with N-acetylcysteine is most effective if started within eight hours of ingestion.

The antidote N-acetylcysteine can be given orally or intravenously. Oral treatment begins with a loading dose of 140 mg/kg followed by 70 mg/kg every 4 hours for 72 hours or 17 doses. The intravenous regimen includes a loading dose of 150 mg/kg over 1 hour followed by 4 hours infusion of 50 mg/kg, and a 16 hours infusion of 100 mg/kg.[29-33]

Amphetamine and Cocaine

Cocaine and amphetamines are widely abused for their euphorigenic and stimulant properties. Both drugs may be smoked, snorted, ingested or injected. Amphetamines and cocaine produce central nervous system (CNS) stimulation and a generalized increase in central and peripheral sympathetic activity.[34] The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous route or smoking.[35] Amphetamine derivatives and related drugs include methamphetamine (Crystal Meth, Crank), MDMA (Ecstasy), ephedrine (Herbal-ecstasy), and methcathinone (Cat).

Toxic effects of cocaine stem from excessive central nervous system stimulation and inhibition of neuronal uptake of catecholamine. Clinical features include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity and psychosis.[36] Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia, may occur.[37] Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection or myocardial infarction.[38] Hyponatremia has been reported after MDMA use. Respiratory complications include status asthmaticus, upper airway obstruction, pulmonary hypertension, barotrauma, pulmonary edema and alveolar hemorrhage.[35,39]

Treatment: The diagnosis is supported by finding amphetamines, cocaine, or the cocaine metabolite benzoylecgonine in the urine. Blood screening is generally not sensitive enough to detect these drugs. Emergency treatment includes the A B C care. Rapidly lower the body temperature in patients who are hyperthermic. Treat agitation, psychosis or seizures with a benzodiazepine, such as lorazepam, 2–3 mg intravenously. Add phenobarbitone 15 mg/kg intravenously for persistent seizures.

Hypertension should be treated with a vasodilator agent, such as phentolamine (1–5 mg intravenously) or a combined alpha- and beta-blockers such as labetalol (10–20 mg intravenously). A pure beta-blocker, such as propranolol should not be used as it may result in paradoxical worsening of hypertension due to unopposed alpha-adrenergic effect.[40]

Tachycardia or tachyarrhythmias should be treated with a short-acting beta-blocker like esmolol (25–100 mcg/kg/min by intravenous infusion).

Aluminium Phosphide Poisoning

Aluminium phosphide is a very common cause of poisoning in North-West and Central India.[41-46] It is available as tablet (3 gram), which contains 56% aluminium phosphide and 44% ammonium carbonate. Toxicity of aluminium phosphide is due to phosphine, which is released when it comes in contact with moisture or hydrochloric acid. The precise cellular mechanism of phosphine is not clear. However, it is stipulated that it acts by preventing the uptake of oxygen by mitochondria.[47] Clinically, a myriad of symptoms are produced by the ingestion of aluminium phosphide. Immediately after ingestion all patients develop nausea, vomiting, retrosternal burning, and in the case of significant poisoning hypotension and shock.[41,43,44,46] Oliguria develops in a few patients. Adult respiratory distress syndrome develops in patients with severe intoxication.[48] Most patients develop myocarditis manifested by variable ECG changes ranging from bradyarrhythmias to tachyarrhythmias. Other complications include disseminated intravascular coagulation, intravascular hemolysis, congestive cardiac failure, hepatic failure and rarely pericarditis. Patients generally remain conscious till cerebral anoxia due to shock supervenes, resulting in drowsiness, delirium and coma.[41,43,49]

Management: The diagnosis is made by the history of ingestion. The diagnosis of aluminium phosphide poisoning can be made by detecting phosphine in exhaled air or in stomach contents.[50] There is no specific antidote for this poisoning and the treatment is supportive. Gastric lavage should be done with potassium permanganate within one hour of ingestion. For management of hypotension, intravenously fluids should be given judiciously as central venous pressure (CVP) is generally high in these patients. If the hypotension does not respond, then dopamine/dobutamine may be used to maintain the systolic BP above 80 mm Hg. Magnesium sulfate, a membrane stabilizer, which can reverse arrhythmias, has been used. Though arrhythmias improve, mortality does not decline. In severe cases, compromised adrenal function has been reported. Though corticosteroids have been administered, the outcome remains poor.[51]

Carbon Monoxide (CO) Poisoning

Carbon monoxide poisoning is seen regularly in clinical practice. It is the third leading cause of unintentional poisoning death in the USA.[52] Precise incidence of CO toxicity in developing countries is not available. Nonfatal incidences far more frequent and misdiagnosis is common.[52] CO poisoning occurs as a result of exposure to internal combustion engines in ill-ventilated places, fires and associated smoke inhalation and industrial accidents. Incidence tends to increase during winter months.

Pathophysiology: CO has 220 times more affinity to hemoglobin (Hb) than oxygen. It binds reversibly to Hb and its dissociation curve runs parallel to oxygen dissociation curve, however they move in opposite directions, i.e. CO curve shifts to right whereas oxygen dissociation curve shifts to left resulting in significant tissue hypoxia.[52,53] It also has higher affinity for myoglobin thereby enhancing myocardial ischemia. CO leads to the activation of platelets and neutrophil, as well as free oxygen radical injury and lipid peroxidation predominantly of the nervous tissue. Therefore, it is not surprising that presenting symptoms of CO toxicity are predominantly neurological and cardiovascular.

Clinical features: Symptoms of toxicity are variable and nonspecific. Careful history of exposure is important. Common patient's complaints include fatigue, nausea, vomiting, dizziness and headache. As the severity increases they develop ataxia, nystagmus, impaired judgment and unconsciousness. They can also develop dysrhythmia, myocardial dysfunction leading to hypotension and metabolic acidosis. Retinal hemorrhage though uncommon, if present strongly indicates CO poisoning. Patients can also have cyanosis and cherry red color of the skin. In pregnant patients, there is an increase risk of fetal death. Later on patients may develop either persistent or delayed neurologic sequelae.

Diagnosis: The diagnosis is confirmed by CO oximetry of the blood, which shows elevation of carboxyhemoglobin (COHb) levels beyond 10%. Severe poisoning is usually associated with levels more than 40%. Pulse oximeter usually gives falsely high values of saturation and must not be relied on in CO toxicity.[54]

Treatment: First of all, patient must be removed from the environment. Rescuer must take all precautions before evacuation. If person is not unconscious, then 100% oxygen with a tight mask with a flow rate of at least 10 L/min should be given. In case the patient is unconscious, he should be intubated and ventilated with 100% oxygen till COHb level reaches 5%. Wherever facility exists/available, hyperbaric oxygen should be preferred in severely poisoned cases.[52,53]

Insecticide Poisoning (Organophosphates, Carbamate, Organochlorine, Herbicide)

There are two major classes of insecticides in usage in commercial agriculture and home gardening, the organophosphates (malathion, parathion) and the carbamate (carbaryl, aldicarb). Insecticides can be absorbed from mouth, skin, conjunctiva, gastrointestinal tract and the respiratory tract. The cause of poisoning varies from suicidal attempt to accidental exposure. Signs and symptoms of acute poisoning generally occur within the first 12 to 24 hours after the exposure.

Organophosphate Poisoning (OP)

Commonly used organophosphates include malathion, parathion, chlorpyrifos, dichlorophos, and phorate. Organophosphates act by inhibiting the enzyme cholinesterase leading to the accumulation of acetylcholine at neuromuscular junction and nerve terminal resulting in the overstimulation of acetylcholine receptors. This initial overstimulation is followed by the paralysis of cholinergic transmission in the central nervous system, in autonomic ganglia, at parasympathetic and some sympathetic nerve endings and in some somatic nerves. A cholinergic crisis results in central and peripheral syndrome. Organophosphates bind irreversibly to cholinesterase, thus inactivating the enzyme through the process of phosphorylation. The aging that is the permanent binding of the organophosphates to the enzyme requires 24 to 48 hours to occur. Once ageing occurs only new enzymatic resynthesis must occur over a period of weeks before the clinical symptoms resolve and normal enzymatic function returns. Organophosphate poisoning can manifest with the varying combinations of symptoms attributed to muscarinic, nicotinic and central disturbances (Table 134.9).

An intermediate syndrome may occur one to four days following an acute organophosphate poisoning.[55] The patient appears to be recovering from acute poisoning when this manifests. Clinically, there is the paralysis of neck flexor muscles, muscles innervated by cranial nerves, proximal limbs and respiratory muscles to the extent that some patient may require respiratory support. Deep tendon reflexes are either absent or markedly diminished. EMG may assist in diagnosis by indicating a problem at neuromuscular junction. Symptoms usually resolve within 4 to 18 days.

TABLE 134.9: Signs and symptoms of organophosphate poisoning

Muscarinic	*Nicotinic*	*Central*

Bradycardia		
Wheezing		

Diagnosis: In most of the developing countries, diagnosis of OP poisoning is largely clinical. However, it can be confirmed by the assays of plasma and Red Blood Cell (RBC) cholinesterases. Plasma cholinesterase assays are more readily available though the estimation of RBC cholinesterases is preferred over serum cholinesterases. Serum and RBC cholinesterase are usually depressed at least 50% below baseline in severe intoxication.

Treatment of organophosphate poisoning: Primarily treatment of OP poisoning includes decontamination, supportive therapy, including mechanical ventilation and definitive therapy in the form of antidotes like atropine and oximes.

i. *Decontamination:* OP compounds are highly lipophilic and are readily absorbed from skin, gut and lungs. Clothes should be removed and patient given a thorough wash with soap and water. Gastric lavage is done routinely, but is not of great help. Activated charcoal single or multiple doses, though found to be effective in animal models of OP poisoning and used routinely preferably within the first hour, is not effective in humans.[56] Airway protection should be a routine whenever lavage is done.

ii. *Supportive therapy:* Large proportion of these patients develops respiratory failure secondary to depolarizing muscle paralysis and overwhelming bronchorrhea. Airway must be protected early (preferably rapid sequence) followed by the control of breathing and circulation. Oxygenation should be started with an aim to have saturations more than 90%. Threshold for the initiation of mechanical ventilation should be low. In the case of seizures, preferred treatment is benzodiazepines (Lorazepam/Diazepam/Midazolam in usual doses) along with atropine.[57]

Respiratory muscle weakness may persist and cause difficulty in weaning, in spite of an apparent improvement in general condition and resolution of symptoms. Therefore, during weaning from ventilator or otherwise in wards, patients need close observation, especially of respiratory and heart rate. Fall in SpO_2 or rise in $PaCO_2$ are the late signs.

iii. *Specific therapy:* Atropine is the specific antidote in organophosphate poisoning. It is usually given in

2–5 mg IV bolus (0.05 mg/kg IV in children). Escalate (double) dose every 3–5 minutes until bronchial secretions and wheezing stops. Once the patient is fully atropinized, i.e. heart rate is more than 80 and secretions are dry; atropine infusion is set up by giving every hour 20 to 30% of the total amount that was required to atropinize the patient initially. The infusion dose is maintained for two to three days for full atropinization, then the infusion dose is daily reduced by 1/4th to 1/3rd of the previous day's dose.[58] Atropine is associated with anticholinergic side effects, including psychosis. Aim of the therapy is to have heart rate more than 80 with the drying of secretions and not dilatation of pupils and gut paralysis (observe abdominal sounds). Glycopyrronium bromide (Glycopyrrolate) can be used in place or together with atropine or if CNS side effects of later develop.[57]

Oximes: Theoretical and experimental basis of the use of oximes in OP poisoning are strong.[59] In humans especially in the case of self-harm, the data for their use is conflicting.[57-61] It has been argued that the efficacy of oximes depends not only on the amount, but also on the nature of compound consumed (dimethyl vs diethyl, former being more resistant), dosages, time of their administration, aging and reactivation kinetics implying there is a therapeutic window during, which oximes may be effective. The window in turn depends on the extent and rate of aging of Acetylcholinesterase (AChE). Further the type of oxime used is also a decisive factor in addition to their dosage (Obidoxime is nine times more active than Pralidoxime). Oximes have their own side effects too. Rapid administration of oxime can cause respiratory arrest in patients having shallow respiration.[62] In the presence of OP compounds they get converted into stable phosphoryl oximes. This further leads to the restriction of their ability to reactivate phosphorylated cholinesterase's and have been blamed for the variable response of oximes in OP toxicity.

In summary, at present evidence on the effectiveness and use of oximes in organophosphate poisoning is mixed. Therefore, it is difficult to contradict the WHO guidelines to give high dose oximes in OP poisoning. As of today, the recommended dosages are Pralidoxime chloride–30 mg/kg bolus followed by 8–10 mg/kg/hr or Obidoxime 250 mg bolus followed by 750 mg/24 hours, until at least 12 hours after the stopping of atropine.[57]

Carbamate Poisoning

Carbamates are cholinesterase inhibitors that are structurally related to the organophosphates. Commonly used carbamates are Sevin, Baygon and Lannate. They transiently and reversibly inhibit cholinesterase enzymes, unlike organophosphates. Regeneration of the ezyme occurs within few hours by the dissociation of the carbamyl-cholinesterase complex. Clinical features of carbamate poisoning are similar to that of organophosphate poisoning, but are of shorter duration. Carbamates do not penetrate the CNS readily, and hence less CNS effects are seen.

Treatment: Cholinesterase levels, thus enzymatic activity usually return to normal within four to six hours, therefore measurement of RBC cholinesterase level is not useful. Initial treatment is similar to that of organophosphate poisoning. Atropine is the antidote of choice and is administered for muscarinic symptoms. There is little need for 2-PAM in carbamate poisoning.[63]

Organochlorine Poisoning[64]

Organochlorine compound includes dichlorodiphenyl-trichloroethane (DDT), chlordane, hexachloro-cyclohexane, eldrin, etc. Organochlorines are well absorbed on ingestion by inhalation and minimally through skin. These agents are CNS stimulants and work by inhibiting GABA and glycine pathways. This leads to the inhibition of chloride channel preventing influx of Cl^- resulting in neuroexcitation, i.e. inhibitory control is lost.[65]

OCL are highly lipid soluble, therefore there is a slow redistribution, prolongation of elimination half life and increased duration of toxicity. Clinical features include the predominance of neurological symptoms ranging from hyperexcitability, irritability, delirium, myoclonus, and facial paresthesias in mild toxicity to seizures and status epilepticus in severe toxicity. In addition, these agents may produce myocardial irritability with ventricular fibrillation.

Management: History is important for making the diagnosis. Laboratory evaluation is generally not helpful, but these agents can be detected in serum and urine. Treatment includes oxygen administration with intubation to treat hypoxia secondary to seizures, aspiration and respiratory failure. Seizures are treated with benzodiazepines (lorazepam 0.04 mg/kg, midazolam 0.05 mg/kg or diazepam 0.2 mg/kg). Phenobarbitone or anesthesia with sodium thiopental may have to be used if the seizure persist. EEG monitoring if available, should be routinely done in these cases to observe seizure activity.

Atropine and epinephrine should be avoided for the control of dysrhythmia in organochlorine sensitized myocardium. Cholestyramine, a bile salt binding substance has been found to be helpful in reducing the absorption of these compounds (4 gm 4 times/day for at least 2–3 days in ingestional poisoning).[66]

Herbicide Poisoning

Herbicides are pesticides used to kill weeds. Herbicides are classified as chlorophenoxy, bipyridyl and urea-substituted compounds. Chlorophenoxy compounds dioxins and furans are the common chemicals under this group. Other agents are 2,4- dicholorophenoxyacetic acid (2,4-D), 4-chloro-2-methylphenoxyacetic acid (MCPA), etc.

The metabolic pathway or mechanism related to toxicity is unknown. Skeletal muscle toxicity can result in respiratory failure or rhabdomyolysis. Toxicity can result from inhalation or ingestion. Clinical features include the eye and mucous membrane irritation. After ingestion, nausea, vomiting and diarrhea occur. Cardiovascular findings include hypotension, tachycardia and dysrhythmias. Muscle toxicity manifests by muscle tenderness, fasciculation and myotonia with resulting rhabdomyolysis.[67]

Treatment: Diagnosis is based on the history of exposure. There is metabolic acidosis and hepatorenal dysfunction. Myoglobinuria and elevated creatinine levels indicate rhabdomyolysis. Treatment is supportive, including decontamination measures and respiratory support. Alkalinization is of any proven benefit however, may be tried in severe toxicity.[68]

Bipyridyl Compound

Paraquat and diquat are nonselective herbicided included in this class. Ingestion is responsible for maximum paraquat-related deaths. Paraquat is distributed to most organs with maximum concentration in the lungs and the kidneys. Acute exposure causes liver and renal necrosis that is followed in weeks by pulmonary fibrosis. Paraquat accumulates in the alveolar cells of the lungs where it is transformed to reactive oxygen species, the superoxide anion. This anion is responsible for lipid peroxidation causing the degradation of the membranes. Paraquat and oxygen enhance each other's toxicity by sustaining the redox cycle. Myocardial injury and necrosis of adrenal gland may occur. Paraquats caustic effects cause local skin irritation and ulceration of the mucous membranes. Hypovolemia occurs due to gastrointestinal losses and decreased oral intake. Cardiovascular collapse may occur early in severe toxicity. Multisystem effects then occur, including gastrointestinal corrosion, acute tubular necrosis and extensive pulmonary injury. Seizures, hepatic failure, gastrointestinal perforation and hemorrhage may occur. Pulmonary fibrosis leading to refractory hypoxemia occurs five days to several weeks later. Metabolic (lactic) acidosis is common as a result of pulmonary effects (hypoxemia) and multisystem failure.[69,70]

Treatment: Early diagnosis and treatment are essential. Diagnosis is based on the history. Qualitative and quantitative analyses for paraquat in serum and urine can help in diagnosis. A 10 hours level of greater than 0.4 mg/l carries a high probability of death.[71] Early treatment is supportive. An attempt at early and vigorous decontamination should be made to prevent superoxide radical formation by using low inspired oxygen to produce a therapeutic hypoxemia with the goal of reducing pulmonary toxicity. The use of low oxygen mixtures ($FiO_2 < 21\%$) with positive pressure ventilation reduces pulmonary toxicity. It is suggested that a higher FiO_2 may only be used when arterial oxygen pressure is less than 40 mm Hg.[72] Maintaining intravascular volumes and urine output are important to prevent prerenal failure. Immediate gut contamination with activated charcoal must be done.[69] Immunosuppressive therapy (cyclophosphamide with dexamethasone) has shown possible benefit in anecdotal reports.[73,74]

Opioids

The term opioids is an all-inclusive term for antagonists, endogenous and exogenous substances that possess morphine like activity. The most commonly abused opioids are heroin and methadone. Prescription and illicit opioids (morphine, codeine, oxycodone, fentanyl, etc.) are popular drugs of abuse and the cause of frequent hospitalizations for overdose.[75-77] These drugs have widely varying potencies and the durations of action; some of the illicit fentanyl derivatives are up to 2,000 times more potent than morphine. All these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Mild intoxication is characterized by euphoria, drowsiness and constricted pupils. More severe intoxication can cause hypotension, bradycardia, hypothermia, coma and respiratory arrest. Pulmonary edema may occur.[78] Death is usually due to apnea or pulmonary aspiration of gastric contents. Propoxyphene may cause the seizure and prolongation of QRS interval.[79] Methadone has been associated with QT interval prolongation and torsades de pointes. With meperidine, the metabolite, normeperidine probably causes seizures and is most likely to accumulate after repeat dosing in patients with chronic kidney disease.[80]

Treatment: Naloxone is a specific opioid antagonist that can rapidly reverse the signs of narcotic intoxication. Although it is structurally related to opioids, it has no agonist effects of its own. It is given at a dose of 0.4–2 mg intravenously and a repeat dose may be given to awaken the patient. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (propoxyphene, codeine, fentanyl derivatives). The duration of the effect of naloxone is only 2–3 hours and repeated doses may be necessary for patients intoxicated by long-acting drugs, such as methadone. Continuous observation for at least three hours after the last dose of naloxone is mandatory.[81] In severest forms associated with respiratory depression, intubation and ventilation may be required.

STINGS AND ENVENOMATION

Snake Envenomation

Snake envenomation is an occupational hazard of farmers, plantation and agriculture workers. Exact incidence in India is not clear, however it is estimated that 35,000–50,000 snake bite deaths occur in India annually.[82] In India, the big four, i.e. Cobra (Naja naja), Common krait (Bungarus coeruleus), Russell's viper (Daboia russelii) and Saw scale viper (Echis carinatus) are responsible for nearly all the reported cases of severe envenomation, as well as death due to snake bites.

Snake venom is a combination of procoagulant enzymes, hemorrhagins, cytolytic or neurotoxins, hemolytic and myolytic phospholipases A_2 and pre/post-synaptic neurotoxins in isolation or in combinations. The net result is myonecrosis, consumption coagulopathy, neuroparalysis leading to life-threatening respiratory paralysis, myocarditis and hypotension, as well as renal failure.[82,83] This explains the diversity of clinical symptoms of the snake envenomation. However, certain patterns are species or genus specific thereby allowing clinical identification and treatment.

Cobra and common krait belong to family elapidae and their bites are primarily responsible for neuroparalytic presentation. Cobra venom acts predominantly postsynaptically whereas Krait venom acts presynaptically and dysautonomia is common. Viperine bites (Russell's viper and saw scale viper) cause severe coagulopathy leading to hemorrhagic manifestations, cardiac toxicity, capillary leak and acute renal failure.[83] There occurs significant local necrosis leading to compartment syndrome. In addition, it is not uncommon to see marked myonecrosis, but it is more common in sea snake bites. In south India and Sri Lanka, neuroparalysis may also be associated with Russell's viper. Cobra bites are associated with significant local necrosis like viperine bites and occasionally with hemolysis.

Clinical Features[82]

Clinical presentation primarily depends on the type of snake and amount of venom injected.

Majority of patients with clinically significant toxicity will have malaise, nausea, vomiting, abdominal pain, drowsiness, weakness and prostration.

Local symptoms are minimal or nearly absent in krait bite. In cobra and viperine bite, there is a swelling at the site of bite, which may expand rather rapidly (Fig. 134.2). It is not uncommon to have regional lymphadenopathy.

Systemic manifestations are usually preceded by significant nausea and abdominal pain. In elapidae bites, patient complains of blurring of vision, double vision, and inability to keep eyes open, drooping of the eyelids followed by difficulty in swallowing, speech and complete bulbar paralysis. The progression of paralysis follows roastrocaudal distribution leading to the development of respiratory and flaccid areflexic paralysis. There occurs complete internal, as well as external ophthalmoplegia (Figs 134.3 and 134.4). In its full blown form, it can mimic brain death with widely dilated nonresponsive pupils. In the Indian subcontinent, snake bite should always be considered as the cause of this presentation especially when it presents acutely even in the absence of history or fang marks as krait usually has little or no local reaction.[84] Recovery occurs in reverse fashion.

Bleeding from the site of bite may be the first manifestation of coagulopathy. Patients can bleed from

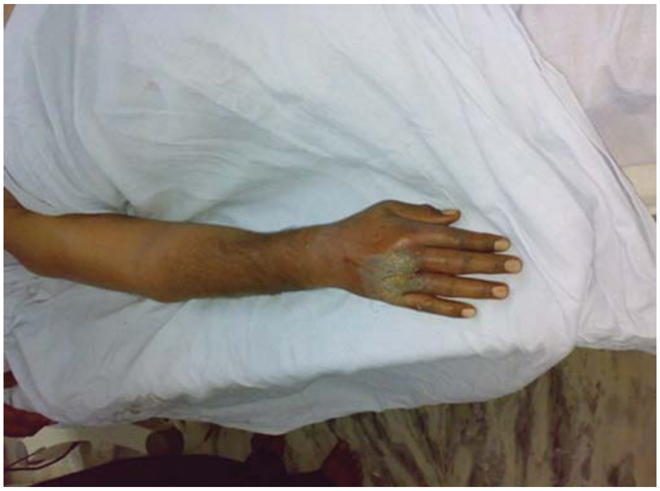

Fig. 134.2: Local signs in cobra bite

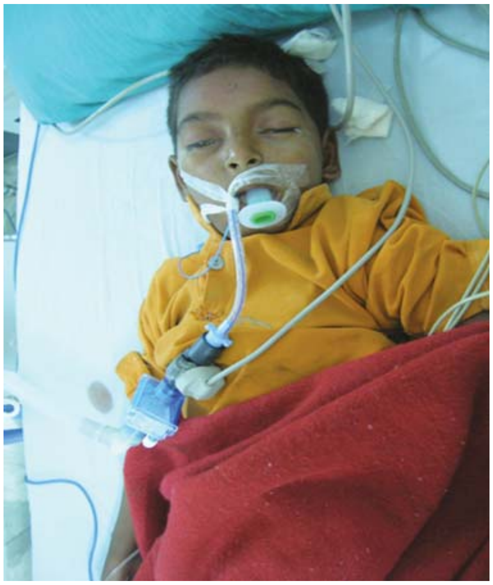

Fig. 134.3: Patient of neuroparalytic snake envenomation with ptosis

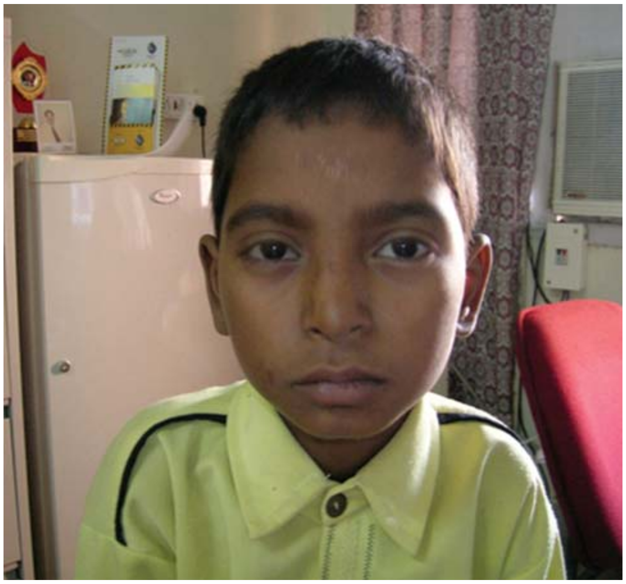

Fig. 134.4: Same patient after recovery

any site, the most dreaded is the intracranial hemorrhage. Due to bleeding, patients can have pituitary apoplexy or acute Addisonian crisis leading to refractory hypotension. Hematuria may be associated with loin pain. Hypotension, cardiac arrhythmias and pulmonary edema are also seen frequently because of the associated toxic myocarditis.

In South India and Sri Lanka, snake bite is a common cause of acute renal failure. It is multifactorial in origin and is characterized by oligoanuria and features of uremia.

Patients may complain of severe muscular pain. Misdiagnosis of acute abdomen has been made in the absence of history. Muscles become tender to touch and rigid. Myoglobinuria, if occurs is characterized by cola colored urine without the evidence of the presence of RBCs.

Investigations

Complete hemogram with platelet counts, Bleeding and Clotting Times (BT and CT) must be done in all patients. Urine should be examined for RBCs in the absence of hematuria. WHO recommend 20 minutes Whole-Blood Clotting Test (WBCT). Failure of blood to clot within 20 minutes signifies significant toxicity. Alternately where facility exists, Prothrombin Time Index (PTI), PTTK, fibrinogen level, creatinine kinase, etc. be done. If urine is smoky and RBCs are absent, myoglobulin should be looked into to rule out myoglobinuria. Electrolytes, blood urea and serum creatinine levels should be regularly monitored in patients with renal failure. Arterial puncture is contraindicated in the presence of coagulopathy.

Treatment

Snake bite is an emergency and usually happens in rural settings where medical facilities are minimal. However, once in the hospital, if severe envenomation is present, the patient should ideally be managed in intensive care (Table 134.10).

The first principal of management is to **do no harm**. Reassure and calm the patient. The limb should be immobilized preferably with a splint and bandage (pressure bandage, if available). Do not apply the bandage if there is a swelling at the site of bite and do not raise the limb. Never-ever open the bandage

TABLE 134.10: Potentially lethal conditions associated with snake bite and its treatment needing

- Circulatory shock, cardiac dysfunction, pulmonary edema
- Hemorrhage, hypovolemia
- Coagulopathy, disseminated intravascular coagulation (DIC)
- Coma, seizures, intracranial hemorrhage
- Cranial nerve dysfunction
- Rhabdomyolysis, renal failure, hyperkalemia
- Gastrointestinal bleeding
- Respiratory failure
- Anaphylaxis (to component of venom or antivenom)

quickly, especially in the absence of life support equipment, as it can lead to sudden deterioration in patient's condition.

The only **specific treatment** for snake envenomation is monovalent or polyvalent antisnake venom (ASV) prepared from horses sera. In India, only polyvalent ASV in both liquid, as well as lyophilized form is available. One ml of reconstituted antivenin neutralizes 0.6 mg venom of Indian cobra and Russell's viper and 0.45 mg of common krait and saw scale viper. Indications for its use are: coagulopathy, neuroparalysis, hypotension/ cardiovascular toxicity, acute renal failure, severe myonecrosis leading to myoglobulinuria and local swelling more than half of the bitten limb (provided not related to ligature) or the local swelling is rapidly enlarging.

Sensitivity must be checked prior to ASV infusion, preferably intradermally. Usually patients are given 50–100 ml of reconstituted ASV in serious envenomation as an infusion over one hour, after premedication with chlorpheniramine maleate (5 mg) and ranitidine (50 mg). It can also be given as a bolus with rate not more than 2 ml/min, especially when the patient is bleeding profusely. Whole blood CT should be repeated every four to six hourly or until the bleeding stops. Recurrence of bleeding after the initial improvement is not uncommon. ASV should be given until clinical bleeding stops and CT normalizes.

ASV will not have a dramatic effect in neuroparalysis. Airway must be protected if patient develops bulbar palsy or has difficulty in swallowing or speaking. Patient must be intubated before giving ASV and ventilated if respiration is shallow or tachypneic. Principles of resuscitation as enumerated in poisoning should take precedence. Low dose ASV is as effective as high dosage in neuroparalytic snake envenomation.[85] Majority of patients usually recover within 48 hours. Mechanical ventilation has reduced the mortality significantly in neuroparalytic envenomation, provided given at appropriate time. In the absence of a ventilator, patient should be managed with manual resuscitators.[86] Anticholinesterase drugs like edrophonium and neostigmine have also been recommended in the treatment of neuroparalytic snake envenomation. They should be given 10 mg of edrophonium or 0.5 mg of neostigmine over 2–3 minutes with atropine to take care of their harmful effect. In case patient improves, he should be managed with neostigmine/atropine over the next 24 to 48 hours.[82,87]

ASV is a foreign protein. Therefore, allergic reactions, including anaphylaxis are not uncommon. True incidence of anaphylaxis is not known as any death or complication is attributed to snake envenomation. Adrenaline syringe should always be kept ready before infusing ASV. In case of anaphylaxis or urticaria, stop the infusion of ASV. It should be followed by adrenaline: usual recommended dosage is 0.5 mg of 1:1000 dilution s/c. Additional dosages of H_1 (Chlorpheniramine maleate) and H_2 (Ranitidine) receptor blockers with hydrocortisone 100 mg, should be given simultaneously. Adrenaline can be repeated up to 2–3 dosages or an infusion can be started in dilution of 1:50,000. Hypotension is also treated with fluids. Inotropes may be required in patients with overt myocardial dysfunction.[82]

Patients developing renal failure need hemodialysis. Hyperkalemia should be looked for and managed aggressively. All patients should be given tetanus immunization. Antibiotics may be given to cover gram-negative organisms and anaerobes (gentamicin and metronidazole or amoxicillin), whenever there is an intense local reaction and swelling.

Snake envenomation, if recognized early and treated aggressively, usually has a good outcome.

Scorpion Sting and Envenomation

Scorpion bite is a common problem in tropics and subtropics. It is commonly associated with outdoor activity. There are more than 90 species of scorpions whom venom is lethal and nearly 50% of them are found in India. In Maharashtra and South Western India, the envenomation is seen entirely after the stings of Mesobuthus tamulus (known as red scorpion), whereas in eastern India it is secondary to Heterometrus bengalensis.[88,89] It is difficult to make any guess estimate of mortality and morbidity in India secondary to scorpion envenomation, but in Mexico more than 1,000 patients are reported to die in a year.[90]

Pathophysiology[91-93]

Unlike snake venom, scorpion venom acts on gated channels primarily the sodium channels leaving them open thereby leading to constant stimulation. Similarly, they also have an effect on calcium dependent K^+ channels in various cells and organs. Venoms effect on presynaptic membranes leads to cholinergic, as well as adrenergic hyperstimulation resulting in the massive release of catecholamines and the stimulation of angiotensin-rennin axis. The autonomic storm is associated with intense vasoconstriction, cardiac stimulation with increased myocardial oxygen demand and marked metabolic abnormalities as in pheochromocytoma crisis ending up in myocardial necrosis and failure. In addition, the activation of cholinergic stimulation also takes place. Therefore, it is not surprising that clinical syndrome is dominated by the features of autonomic crisis, including severe cardiovascular effects and cholinergic stimulation.

Clinical Features

Clinical signs and symptoms depend primarily on the amount of venom released in the body. If accidentally the venom is injected in the veins, presentation of envenomation can occur in as little as 5–10 minutes. There occurs intense severe pain at the site of sting. It worsens on taping at the site of bite (Tap sign) and may be associated with burning and paresthesiae. Systemic envenomation is characterized in the initial stages by tachycardia and hypertension. There may be sweating, lacrimation and fasciculations. In severe envenomation, patient develops pulmonary edema, dysrhythmias, hypotension, which becomes refractory later. Muscle paralysis and priapism are also not uncommon to see.

Investigations

EKG: The most common abnormality is sinus tachycardia, which is universal. Overtime, one can see QTc prolongation, and ST-T changes, including T inversions. In 10 to 12% of patients, conduction blocks may also be present.

Echocardiography: In patients with moderate to severe toxicity, it shows global left ventricular hyperkinesias, which return to normal after recovery.

Pulmonary artery (PA) studies: Demonstrate elevated systemic vascular resistance (SVR), which may be increased up to four times with low cardiac index and elevated filling pressures.

CXR: Shows cardiomegaly with evidence of pulmonary edema.

Biochemical: Hyperglycemia and elevated levels of FFA are common.

Coagulation parameters and blood gases should be done when necessary.

Treatment

Scorpion bite is an emergency and patients with systemic manifestations must preferably be managed in critical care units.

i. *Local:* Immobilize the affected part and keep it below the heart. Lymphatic venous compression may be applied an inch proximal to the bite to prevent venoms absorption. Like snake envenomation, it should be removed when one is in position to provide life-sustaining support.[90]

   Pain can be relieved by giving ice packs, as well as analgesics. Ice packs are most effective when applied earlier, preferably within two hours of sting.

ii. *Systemic:* General: Primary aim is to resuscitate and stabilize. One must follow the principles of resuscitation, i.e. establish airway, breathing, and circulation and shift the patient to intensive care for monitoring. Administer oxygen and maintain saturations to more than 90%. Fluids should be administered to prevent hypovolemia, which is not uncommon in these seriously sick patients.

Specific

Antivenin is the treatment of choice and should be administered at the first opportunity after stabilization of the patient. The usual starting dose is 10 ml of the reconstituted ASV and can vary from 10 to 30 ml or more depending on the severity and evolution of toxicity; 1 ml neutralizes approximately 13–17 mg of crude venom.[93] Antivenom neutralizes only the free venom therefore ongoing toxicity may continue. Either one has to use more ASV or preferably use prazosin (which is a postsynaptic alpha-2 blocker), which reverses most of the effects of the venom.

Combination of sympathetic alpha-blocker (Prazosin) with beta-blocker is most effective in reversing the effect of venom in patients who primarily have hyperdynamic cardiovascular changes manifested by tachycardia and hypertension.[90] Beta-blockers must never be used alone. Golden rule is to treat the condition like pheochromocytoma crisis. Prazosin alone has decreased the mortality from 30 to 40% to less than 3%. Therefore, if ASV is not available then patient must preferably be treated with Prazosin.[94]

Insulin-glucose-K^+ infusion, as well as other antihypertensive like nifedipine, captopril and others have also been used. People have also used nitroprusside and nitroglycerin to reduce the after-load. All patients must receive antitetanus prophylaxis.

ENVIRONMENTAL INJURIES

Environmental injuries are commonly seen in medical practice. While hypothermia is common during winters and at high altitudes, hyperthermia is commonly seen during the summer months in humid tepid and warm working environment when temperature may go as high as 45° centigrade. Increased outdoor activities, such as excursions, swimming, travel and accidents add to the growing number of people involved in injuries requiring life supporting treatment. Environmental injuries may also result from occupational hazards, such as in armed forces personnel posted at high altitude in deserts.

Hypothermia

Definition

Primary or accidental hypothermia can be defined as unintentional decrease in core body temperature probably due to cold environment exposure.[95] It can also be defined as core temperature less than 35ºC (95.0ºF). Hypothermia is further defined as mild (35–32ºC), moderate (32–28ºC) or severe (<28ºC).

Epidemiology

People in extremes of age, military combatants and winter sport participants are common risk population. Dehydration, malnutrition and certain common drugs like β-blockers, calcium channel blockers, antibiotics can also contribute to cause hypothermia. It may also be seen in endocrinopathies like hypothyroidism, postoperative states and alcohol intoxication.

Pathophysiological Changes

Hypothermia is caused when normal heat generating mechanism by posterior pituitary and heat conservation mechanism by anterior pituitary are disturbed by extreme cold exposure. Every organ shows changes due to the effects of hypothermia.

The initial response of cold stress on cardiovascular system is peripheral vasoconstriction with tachycardia and increased myocardial oxygen consumption. There is also associated increase in blood pressure.[96] As temperature goes down to 28°C, myocardial depression ensues resulting into bradycardia, decrease in cardiac output and index (with resultant QRS broadening and prolongation of QT segment) and hypotension. Atrial and ventricular arrhythmias occur with profound hypothermia. J wave or Osborn wave,[97-98] present at the junction of QRS and ST segment, marked in lead II and V6, is diagnostic of hypothermia when temperature goes down to 32ºC.

Cerebral metabolic activity decreases linearly as hypothermia sets in.[99] Cognitive functions are the first to be affected. EEG activity slows as temperature goes down and is totally silent by 19–20ºC. Triphasic waves are characteristic in electroencephalogram of hypothermia.

Initial hyperventilation is followed by hypoventilation, increased secretions, ventilation perfusion mismatch, noncardiogenic pulmonary edema, acute respiratory distress syndrome and lastly respiratory arrest. Below 30ºC, respiratory rate is generally slow at 5–10/min.

Renal system responds by cold diuresis probably due to the inhibition of ADH release.

Coagulopathies are frequent during hypothermia. Prolongation of activated partial thromboplastin time with normal prothrombin time and normal international normalized ratio occur up to temperatures of 30ºC whereas below this temperature, picture of disseminated intravascular coagulopathy with thrombocytopenia sets in. Leukocytosis with hemoconcentration occurs secondary to volume contraction from diuresis.

Treatment

Principles of resuscitation, i.e. ABC should take precedence followed with careful rewarming under observation.

Rewarming: Method of rewarming depends on the severity of hypothermia and should be accompanied with adequate cardiac and hemodynamic monitoring. Passive external rewarming, active external rewarming or active core rewarming are the accepted methods.[100] Removing the stable patient from cold exposure forms passive external rewarming.[101,102] This method is generally employed at the prehospital scene.

Active external rewarming is done by creating heated environment around the patient by using heating pads, warm blankets, infrared lights or immersion in warm water. It raises the body temperature by 0.5–0.6ºC/hour. This method is controversial as it results into a phenomenon called core temperature after drop, which is decrease in core temperature due to sudden peripheral vasodilatation resulting at times into life-threatening arrhythmias.

Active core rewarming is the method of choice in severe hypothermia and is done by infusing warm intravenous fluids of up to 42ºC, body cavity warm lavages, inhalation of heated air or by extracorporeal circuit. This method is best in increasing body temperature to the magnitude of 1–2ºC/hour.

Associated conditions must be identified and treated. In the cases of myxedema coma leading to hypothermia, thyroxine along with steroids must be given.

In spite of aggressive management, mortality with hypothermia continues to be high.

Hyperthermia

Hyperthermia is defined as increase in body temperature with abnormal thermoregulation. There is a wide spectrum of heat-related illnesses extending from heat cramps or miliaria rubra to life-threatening heat exhaustion and heat stroke.

Heat exhaustion is generally present in individuals who sweat profusely during extreme environment heat load, thus become hypovolemic.[103] The symptoms are generally vague, such as general irritability, fatigue, increased thirst, decreased urine output and light headedness. Muscle cramps occur later in the course of the illness. Temperatures are generally elevated, readings up to 40ºC have been seen. Rhabdomyolysis does not occur in heat exhaustion. Treatment consists of exposing the individual to cool environment and aggressive fluid resuscitation.[104] Encourage oral intake in conscious patients, if patient has vomiting, then intravenous fluids should be administered.

Heat stroke is a medical emergency. It can be differentiated from heat exhaustion by temperature elevation of more than 40.6ºC and associated CNS symptoms. Another peculiar symptom is the absence of sweating. This syndrome is also associated with multiorgan failure with rhabdomyolysis, Disseminated Intravascular Coagulation (DIC) and renal failure. These patients have classical CNS symptoms[105] like agitation, delirium, hallucinations, convulsions and lastly coma. They have cerebral edema on autopsy. Tachycardia is a universal finding; low cardiac output with hypotension refractory to volume loading and vasopressors is characteristic.[106,107] High-grade fever stimulates respiratory center leading to hyperventilation, respiratory alkalosis, hypocalcemia and tetany. Acute renal failure and the elevation of hepatic enzymes are seen in approximately 25 to 30% of patients probably due to thermal cell injury. Vomiting and diarrhea are common. Patches of gut ischemia can occur due to compensatory mesenteric vasoconstriction.[108] Thrombocytopenia with DIC resulting into petechial hemorrhages, hematuria, and alveolar hemorrhage is a common feature of heat stroke.

Heat stroke is of two types—classic heat stroke is due to environment exposure and exertional heat stroke is after strenuous exercise, mostly in hot humid environment. Exertional heat stroke is the severe form and has higher incidence of multiorgan dysfunction and mortality.

Management

After addressing to airway and breathing, fluid resuscitation should be done. Cold intravenous fluids can be used.[109] Cooling of the patient should be undertaken. The aim of any cooling method is to bring down the temperature to 39ºC.[110] External cooling is the most common and the easiest method. This is achieved by placing the patient in cool environment and by putting ice packs in groins, axillae and over the chest. Pouring tap water over the body and fanning the patient will also decrease temperature by evaporative cooling. Cool water immersion[111] is one of the commonest methods of cooling. Internal cooling can be done by lavages of body cavities by cool water. Blood samples to check for multiorgan dysfunction should be taken.[112]

Drowning and Near Drowning

World Health Organization defines drowning as "the process of experiencing respiratory impairment from submersion or immersion in liquid."[113] Some of the important situations, which have been identified to lead to drowning include unattended children, alcohol abuse, restricted swimming capability, exacerbation of pre-existing conditions (seizure, myocardial infarction), risky behavior, exhaustion and others.[114] Children form the major bulk of patients.

Drowning is a continuum of events, which occur when the victim's airway lies below water.[115-117] It starts with breath holding leading to laryngospasm and resultant respiratory acidosis and hypoxemia. This progresses to the respiratory efforts and drinking of large quantities of water in lungs causing severe acid-base changes and finally respiratory arrest. Drowning is associated with cerebral edema and raised Intracranial Pressure (ICP), acute respiratory distress syndrome, noncardiogenic pulmonary edema, myocardial dysfunction, cardiac arrhythmias, acute tubular necrosis, hepatocellular damage and hypothermia. These patients generally have hypoxic-ischemic injury.

Management

Basic cardiopulmonary resuscitation after drowning/near drowning and the treatment of pulmonary edema remains the mainstay of treatment.

Treatment starts at the site of submersion injury. The main objective of prehospital management is to restore normal ventilation, circulation and acid-base balance.[118] Cardiopulmonary resuscitation should be started by the bystander until health care personnel arrive. Cardiopulmonary resuscitation has the same principles as for other patients.[119] Cold wet clothes should be removed from the victim's body. Airway and breathing should be addressed immediately. Cervical spine immobilization should be undertaken. If patient does not breathe adequately, then breathing should be controlled by intubation and ventilation. Once the patient reaches the hospital, controlled ventilation with the low levels of Positive End Expiratory Pressure (PEEP) should be used initially. Generally, these patients have pulmonary edema, so noninvasive ventilation with Continuous Positive Airway Pressure (CPAP) can also be used.[120] Invasive monitoring is generally not required. Methods to measure core temperatures should be employed. ICP monitoring has a limited role in management. Antibiotics become useful only for those patients who become febrile after drowning in sea water.

Inhalational Injury

Inhalational injuries and smoke inhalation are not common. It is of more serious nature in burns in children.[121] The combination of burn injury and inhalational injury increase mortality by 44%. Inhalational injuries should be identified early, which can be due to: i. direct injury to the airways; ii. carbon monoxide poisoning; iii. toxic fumes, like cyanide; or iv) acute asphyxia.

Pathophysiology

Inhalational injury generally follows a three phase course:

Initial phase: There are signs of carbon monoxide poisoning (headache, nausea, irritability, decreased visual aquity, confusion, seizure) with features of toxic fume poisoning. Pulmonary edema with airway obstruction is not uncommon.

Second phase: Features of ventilation-perfusion mismatch and hypoxemia start appearing and patient may develop acute respiratory distress syndrome.

Final phase: Pneumonias and pulmonary embolism may occur after the initial phases.

Management

These patients pose a real challenge as far as their airway management is concerned. A normal looking patient after a burn injury can suddenly develop respiratory distress. Dry heat produces edema of the oral cavity and larynx leading to respiratory obstruction. All inhalational injury patients presenting with stridor should be immediately intubated in the view of impending respiratory failure. Patients with inhalational injury should be given 100% oxygen to treat carbon monoxide poisoning.[122,123] If arterial saturation is not maintained above 90%, conventional ventilation should be initiated and treatment protocol of ARDS should be started.[124-127] For patients who are refractory to conventional ventilation, extracorporeal oxygenation[128] or nitric oxide inhalation can be tried.

Tracheobronchial toilet with fiberoptic bronchoscope should be done to clear out burn debris and sloughed mucosa. Strategies[129] to prevent pneumonia (e.g. head elevation of the bed by 30°), stress ulcer and deep vein thrombosis prophylaxis must be initiated from the very beginning. There is no role of prophylactic antibiotic administration. Corticosteroids whether inhaled or intravenous are detrimental in burn patients as they increase the chances of superadded infections.

Summary

Environmental hazards can manifest after natural or man-made disasters and can lead to huge resource utilization. The presentation and management of each injury has a characteristic course and if timely protocolized management in followed the results can be awarding.

Obstetric Critical Care

Hrishikesh S Kulkarni, Dilip R Karnad, Kalpalatha K Guntupalli

INTRODUCTION

Critically ill patients comprise nearly 7% of all admissions to Indian intensive care units (ICUs).[1] Studies in Asian ICUs show that 120 to 730 obstetric patients are admitted to the ICU per 100,000 deliveries.[2] Poor preexisting nutritional status of the patient and anemia, low socioeconomic status of the family, lack of access as well as delay in receiving appropriate antenatal health care, unhygienic deliveries and increasing numbers of operative interventions lead to unique problems in the developing countries. Managing critically ill obstetric patients is a challenge for the intensivist, who needs to ideally ensure the well-being of both the mother and the fetus. Among other things, the intensivist needs to consider the physiological changes of pregnancy while interpreting the results of diagnostic tests. The intensivist also needs to assess the safety profile of prescribed medications, and needs to modify the dose where appropriate due to the different pharmacokinetics (absorption, distribution, metabolism and elimination) during pregnancy. A database of the safety profile of different medications in pregnancy is available online at http://www.safefetus.com.[3]

The causes of ICU admissions in pregnant patients can be divided into obstetric (defined as "those admissions that would not have occurred in a nonpregnant patient") and medical (Table 135.1).[4]

TABLE 135.1: Conditions requiring intensive care unit admission in critically ill obstetric patients in developing countries

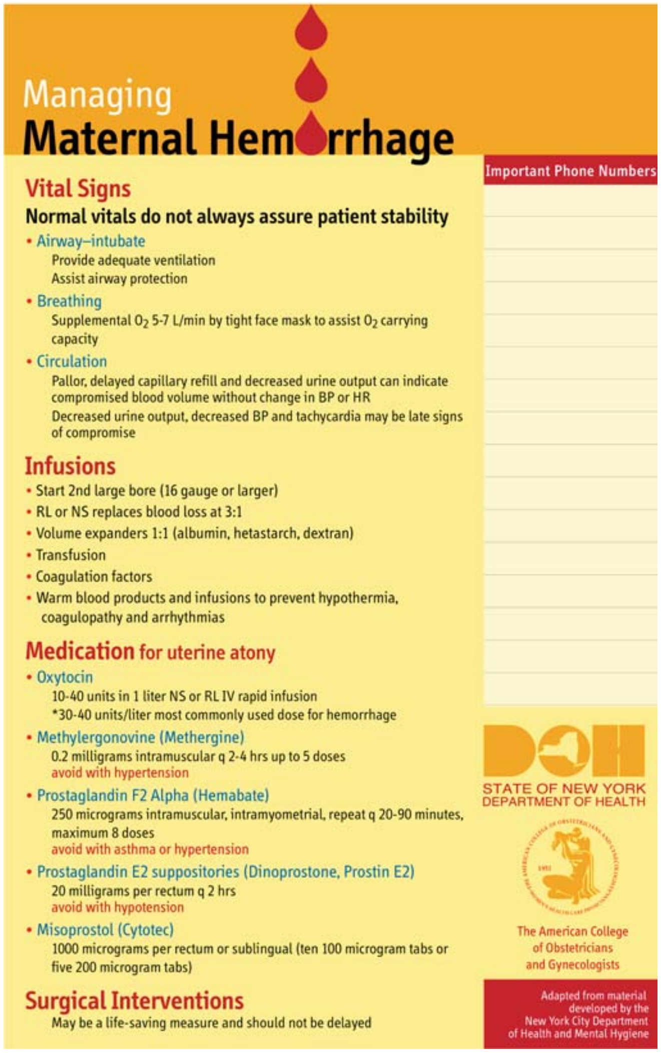
Obstetric	*Incidence (%)*	*Medical*	*Incidence (%)*
Pre-eclampsia/eclampsia	45.5	Malaria	10
Postpartum hemorrhage (PPH)	15.3	Viral hepatitis	6.2
Intrauterine fetal death (IUFD)	12.5	Cerebral venous thrombosis	3.5
Postabortal/puerperal sepsis	6.5	Community-acquired pneumonia	3.1
HELLP syndrome	5.6	Aspiration pneumonia	3.1
Abruptio placentae	5.7	Cardiac arrest prior to ICU admission	2.8
Acute fatty liver of pregnancy (AFLP)	4.4	Rheumatic heart disease	2.1
Antepartum hemorrhage	3.6	Diabetes mellitus	2.1
Abortions	2.4	Bacteremia	1.7
Abnormal adherence of placenta	1.1	Attempted suicide (poisoning/drugs)	1.7
Uterine rupture	0.8	Hematologic disorder	1.6
Chorioamnionitis	0.9	Intracranial hemorrhage	1.2
Peripartum cardiomyopathy	0.5	Endocrine	1.1
Amniotic fluid embolism	0.5	Central nervous system infection	0.8
		Tetanus, leptospirosis, typhoid	0.7
		Deep vein thrombosis/pulmonary embolism	0.7
		Chronic renal failure	0.5

Severity scores, such as the APACHE II and SAPS II often overestimate the risk of mortality in critically ill obstetric patients, especially in those with "obstetric disorders." Interestingly, among ICU patients with similar conditions (e.g. sepsis), pregnant patients often do better than the nonpregnant patients.[2] Precedence should be given to maternal well-being, resuscitation and stabilization of the mother often results in the external manifestations of fetal distress (like persistent fetal tachycardia, decreased variability and late decelerations on external cardiac monitor) returning to normal, and improves fetal survival. The next few pages briefly describe what the intensivist can do in the management of critically ill obstetric patients, while coordinating with the obstetrician and neonatologist, to improve maternal and fetal outcomes.

OBSTETRIC HEMORRHAGE

Obstetric hemorrhage occurs either antepartum (4 to 10% of pregnancies) or postpartum (10 to 20% of deliveries).[2,4,5] Common antepartum causes include placenta previa, abruptio placentae, vasa previa, ruptured ectopic pregnancy and uterine rupture.[6] Postpartum bleeding is most commonly due to uterine atony, retained placenta, uterine rupture, uterine inversion or genital ulcerations.[5] Postpartum bleeding is significant when there is over 500 mL of blood loss within 24 hours of delivery, a drop of more than 10% in the hematocrit since admission, or when the blood loss leads to hemodynamic instability.[5]

Obstetric hemorrhage should be managed immediately because the patient's condition can deteriorate rapidly.[7] Clinicians underestimate the degree of loss, and the clinical signs and symptoms should be used to guide the management (rather than the amount of external bleeding).[7] For every 1 mL of blood loss, 3 mL of fluid needs to be given through one or two large bore intravenous cannulae (14 or 16 gauge). Colloids can possibly worsen coagulation.[8] The American College of Obstetricians and Gynecologists and the New York State Department of Health have developed a poster that is useful in the initial management of obstetric hemorrhage (Fig. 135.1).[9] As the patient is being resuscitated, the obstetrician and neonatologist need to be informed immediately. These patients also need continuous cardiac monitoring, because the hemorrhage can precipitate myocardial ischemia.[10] If the fetus has yet not been delivered, start continuous electronic fetal monitoring as soon as possible.



Managing

Maternal Hemorrhage

Important Phone Numbers

Vital Signs

Normal vitals do not always assure patient stability

- Airway–intubate
  - Provide adequate ventilation
  - Assist airway protection
- Breathing
  - Supplemental O_2 5-7 L/min by tight face mask to assist O_2 carrying capacity
- Circulation
  - Pallor, delayed capillary refill and decreased urine output can indicate compromised blood volume without change in BP or HR
  - Decreased urine output, decreased BP and tachycardia may be late signs of compromise

Infusions

- Start 2nd large bore (16 gauge or larger)
- RL or NS replaces blood loss at 3:1
- Volume expanders 1:1 (albumin, hetastarch, dextran)
- Transfusion
- Coagulation factors
- Warm blood products and infusions to prevent hypothermia, coagulopathy and arrhythmias

Medication for uterine atony

- Oxytocin
  - 10-40 units in 1 liter NS or RL IV rapid infusion
  - *30-40 units/liter most commonly used dose for hemorrhage
- Methylergonovine (Methergine)
  - 0.2 milligrams intramuscular q 2-4 hrs up to 5 doses
  - avoid with hypertension
- Prostaglandin F2 Alpha (Hemabate)
  - 250 micrograms intramuscular, intramyometrial, repeat q 20-90 minutes, maximum 8 doses
  - avoid with asthma or hypertension
- Prostaglandin E2 suppositories (Dinoprostone, Prostin E2)
  - 20 milligrams per rectum q 2 hrs
  - avoid with hypotension
- Misoprostol (Cytotec)
  - 1000 micrograms per rectum or sublingual (ten 100 microgram tabs or five 200 microgram tabs)

Surgical Interventions

May be a life-saving measure and should not be delayed

Fig. 135.1: Management of obstetric hemorrhage

While stabilizing the vital signs, look for the cause by initially examining the external genitalia. In the case of postpartum hemorrhage, first check the tone of the uterus. Handling of the uterus needs to be done by an experienced physician/obstetrician, because the unnecessary kneading of a firm uterus can lead to the worsening of the bleeding.[11] If the uterus is contracted, rule out genital lacerations by inspecting the vagina, cervix and uterus. These are the most common causes of postpartum bleeding.[5] Massive bleeding from genital lacerations suggests the involvement of a major vessel. In rare cases, genital lacerations may lead to unexplained hemodynamic instability. In these cases, rule out a retroperitoneal hematoma. Some of these patients may even need an exploratory laparotomy.[5] Patients with retroperitoneal hematomata generally present with fever, thigh pain, leg edema and/or ileus within 24 hours of delivery. [12] The alternate possibility in a patient with a contracted uterus is a retained placental fragment.[11]

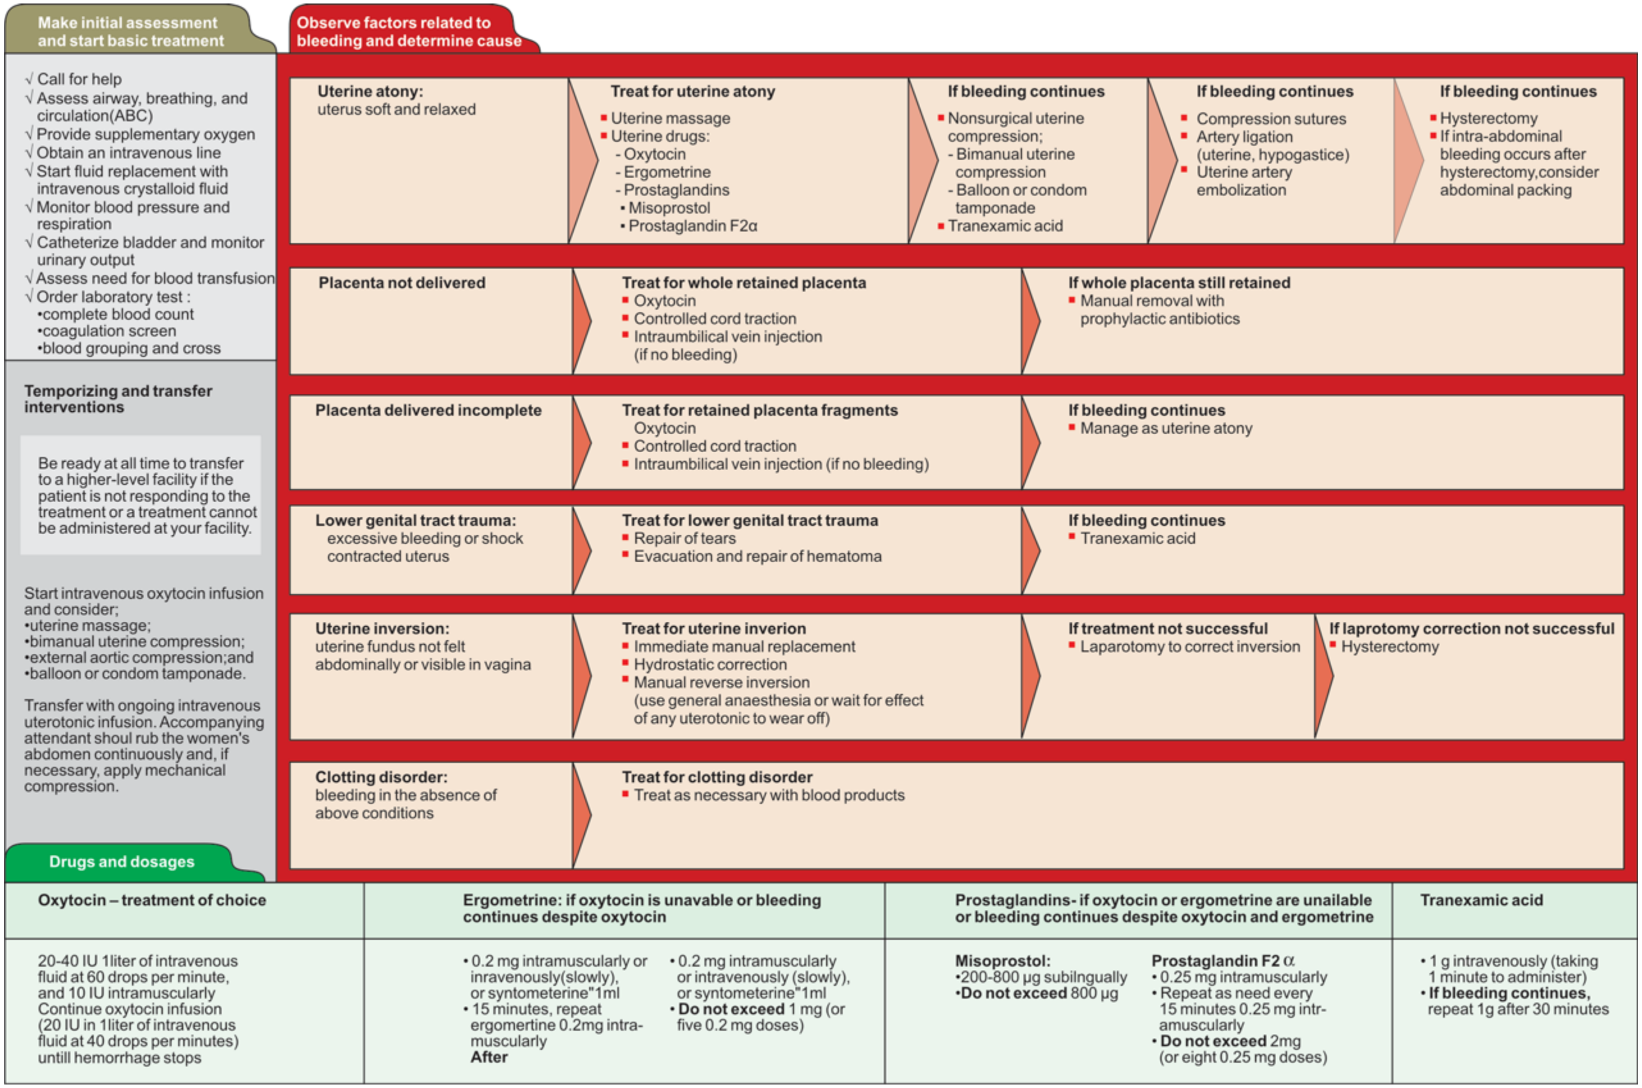
Always be wary of precipitating a massive hemorrhage when exploring the uterus for a retained placental fragment.[5]

If the uterus is atonic, first discontinue uterine relaxants like tocolytics, inhalational anesthetics and empty the patient's bladder.[10] Prompt, yet carefully monitored initiation of an uterotonic agent like oxytocin is essential. Further management of the different etiologies and the recommended drug doses are described in Figure 135.2. In addition to the steps in Figure 135.2, alert the blood bank and have at least four units of typed and cross-matched blood, two units of fresh frozen plasma and one ten-pack of platelets ready for transfusion (if necessary); the lab should always stay four units ahead of blood use.[13] The first unit of cross-matched blood should be obtained within 30–45 minutes. [14] Table 135.2 gives a list of blood products. Meanwhile, O negative red blood cells (RBCs) can be used on an emergency basis, because continued dependence on fluids can dilute the coagulation factors.[14] Every unit should have a readily available tray containing the essential drugs for the management of primary postpartum hemorrhage (PPH).[7] If the bleeding continues in spite of medical management, uterine massage, followed by temporary tamponade can be achieved (before the obstetrician arrives) by passing the balloon of a Foley's catheter or a Sengstaken-Blakemore tube past the cervical canal and inflating it (generally with 60–80 mL of saline) till the bleeding stops.[15,16] This is also a useful diagnostic test to decide if the patient needs an emergency laparotomy.[17] The maximum time the balloon can be left inflated is 48 hours. Thrombophilias like von Willebrand's Disease (vWD) may be unmasked in pregnancy.[18] Treat such patients using tranexamic and/or deamino-delta-D-arginine vasopressin (DDAVP), followed by factor replacement (Table 135.2). Recombinant-activated factor VII (initial bolus dose of 90 mcg/kg followed by a second identical dose if no response is seen) has shown promise as an adjunctive measure in obstetric hemorrhage, but the lack of randomized control trials precludes its routine use.[10,19]

Placental abruption occurs when the normally implanted placenta separates (partially or completely) from its basal layer before the delivery of the fetus. Placental abruption may lead to either frank or concealed hemorrhage and uterine atony that when untreated, leads to hypovolemia-induced end-organ damage (e.g. acute kidney injury, Sheehan's syndrome) and disseminated intravascular coagulation.[5] Increasing uterine tenderness, uterine contractions, maternal tachycardia and the evidence of hemodynamic instability are warning signs.[6] An emergent vaginal ultrasound can help delineate the degree of separation; however, only 50% of the hemorrhages due to abruptio placentae can be detected by ultrasound—hence, it is more of use for ruling in than ruling out. Stable patients with placental abruption can be managed conservatively, waiting for normal vaginal delivery if the pregnancy is less than 36 weeks. [6] However, deteriorating maternal or fetal status may warrant an emergency cesarean section. In nonresponsive cases, a hysterectomy is the last resort. Placental abruption used to carry 20 to 40% mortality, but this has reduced in recent years to 5 to 10%.[20,21] Yet, placental abruption can lead to adverse neurologic sequelae in the infant.[22]

Placenta previa, in which the placenta abnormally implants over the lower uterine segment, leads to painless frank antepartum bleeding because the progressive cervical dilatation and lengthening causes shearing of the placenta.[5] It may also be precipitated by minor trauma or sexual intercourse.[6] Most cases stop spontaneously, but hemodynamically unstable mothers may need cesarean section. An increased incidence of abnormal fetal positions may occur —another reason for the obstetrician to be involved early. Careful monitoring of the mother is necessary even after the bleeding has stopped, because it may recur at any time. Vasa previa involves bleeding from the vessels that cross the internal os before entering the placenta. The bleeding is entirely fetal and generally happens when the membranes rupture; thus these patients will generally not present in the medical intensive care unit (MICU) unless there is preterm labor in an already admitted patient. However, if it occurs, consider an emergency cesarean section followed by fetal transfusions and volume resuscitation by the neonatologist if the fetus is alive.[6] Patients having a ruptured ectopic pregnancy may not necessarily have torrential bleeding; however, an acute abdomen in the presence of any amount of vaginal bleeding should prompt the physician to explore this diagnosis. Diagnosis is by emergency transvaginal ultrasound and if confirmed, immediate surgical repair is warranted.[23]

Uterine rupture occurs in those patients having a history of uterine scarring (e.g. cesarean section, myomectomy), especially in that subset who attempt a vaginal delivery or in whom uterotonic agents are used. However, it may occur in a primigravida as well.[10] A part or whole of the fetus enters the peritoneal cavity. Severe abdominal pain may be deceptively absent, and the blood loss is moderate; therefore, a nonreassuring fetal heart rate pattern that is eventually lost should alert the attending physician to this



Make initial assessment and start basic treatment

√ Call for help
√ Assess airway, breathing, and circulation(ABC)
√ Provide supplementary oxygen
√ Obtain an intravenous line
√ Start fluid replacement with intravenous crystalloid fluid
√ Monitor blood pressure and respiration
√ Catheterize bladder and monitor urinary output
√ Assess need for blood transfusion
√ Order laboratory test :
•complete blood count
•coagulation screen
•blood grouping and cross

Temporizing and transfer interventions

Be ready at all time to transfer to a higher-level facility if the patient is not responding to the treatment or a treatment cannot be administered at your facility.

Start intravenous oxytocin infusion and consider;
•uterine massage;
•bimanual uterine compression;
•external aortic compression;and
•balloon or condom tamponade.

Transfer with ongoing intravenous uterotonic infusion. Accompanying attendant shoul rub the women's abdomen continuously and, if necessary, apply mechanical compression.

Observe factors related to bleeding and determine cause

Uterine atony: uterus soft and relaxed

Treat for uterine atony
- Uterine massage
- Uterine drugs:
  - Oxytocin
  - Ergometrine
  - Prostaglandins
    - Misoprostol
    - Prostaglandin F2α

If bleeding continues
- Nonsurgical uterine compression;
  - Bimanual uterine compression
  - Balloon or condom tamponade
- Tranexamic acid

If bleeding continues
- Compression sutures
- Artery ligation (uterine, hypogastice)
- Uterine artery embolization

If bleeding continues
- Hysterectomy
- If intra-abdominal bleeding occurs after hysterectomy,consider abdominal packing

Placenta not delivered

Treat for whole retained placenta
- Oxytocin
- Controlled cord traction
- Intraumbilical vein injection (if no bleeding)

If whole placenta still retained
- Manual removal with prophylactic antibiotics

Placenta delivered incomplete

Treat for retained placenta fragments
Oxytocin
- Controlled cord traction
- Intraumbilical vein injection (if no bleeding)

If bleeding continues
- Manage as uterine atony

Lower genital tract trauma: excessive bleeding or shock contracted uterus

Treat for lower genital tract trauma
- Repair of tears
- Evacuation and repair of hematoma

If bleeding continues
- Tranexamic acid

Uterine inversion: uterine fundus not felt abdominally or visible in vagina

Treat for uterine inverion
- Immediate manual replacement
- Hydrostatic correction
- Manual reverse inversion (use general anaesthesia or wait for effect of any uterotonic to wear off)

If treatment not successful
- Laparotomy to correct inversion

If laprotomy correction not successful
- Hysterectomy

Clotting disorder: bleeding in the absence of above conditions

Treat for clotting disorder
- Treat as necessary with blood products

Drugs and dosages

Oxytocin – treatment of choice	Ergometrine: if oxytocin is unavable or bleeding continues despite oxytocin	Prostaglandins- if oxytocin or ergometrine are unailable or bleeding continues despite oxytocin and ergometrine	Tranexamic acid
20-40 IU 1liter of intravenous fluid at 60 drops per minute, and 10 IU intramuscularly Continue oxytocin infusion (20 IU in 1liter of intravenous fluid at 40 drops per minutes) untill hemorrhage stops	• 0.2 mg intramuscularly or inravenously(slowly), or syntometerine"1ml • 15 minutes, repeat ergomertine 0.2mg intra-muscularly **After** • 0.2 mg intramuscularly or intravenously (slowly), or syntometerine"1ml • **Do not exceed** 1 mg (or five 0.2 mg doses)	**Misoprostol:** •200-800 μg subilngually •**Do not exceed** 800 μg **Prostaglandin F2** α • 0.25 mg intramuscularly • Repeat as need every 15 minutes 0.25 mg intr-amuscularly • **Do not exceed** 2mg (or eight 0.25 mg doses)	• 1 g intravenously (taking 1 minute to administer) • **If bleeding continues,** repeat 1g after 30 minutes

Fig. 135.2: Management of postpartum hemorrhage as per WHO guidelines (2009)
(Obtained with permission from the World Health Organization)

TABLE 135.2: Resuscitation of obstetric patients using blood products

Replacement	*Indication*	*Dose*	*Expected effect*	*Comment*
Packed RBCs (PRBC)	Severe anemia	1 U contains 250-325 mL	1 U increases: Hct by 3% Hb by 1%	• Use O negative cells initially if necessary· • Use a blood warmer to prevent hypothermia· • Use leukoreduced blood to prevent febrile reaction
Platelets	1. Active bleeding platelets <50,000. 2. No active bleeding + platelets <30,000*	1 U contains 35-50 mL	1 U increases total platelet count by 8,000/mm^3.	• Can be stored for up to 5 days at 20-24°C.
Fresh frozen plasma (FFP)	Active bleeding + prolonged PT/aPTT (> 1.5 × normal)	1 U contains 200-400 mL; use 1 U of FFP per 1 U of PRBC	250 mL will increase total fibrinogen by 25 mg/dL	• Can be stored up to 2 hours when thawed· • If it leads to fluid overload, use (nonactivated) prothrombin complex concentrate
Fibrinogen	Fibrinogen deficiency (<1-1.5 mg/dL)		4 g concentrate raises levels by 10 mg/dL	• May have potential viral contamination – use pasteurized concentrates
Cryoprecipitate	Hemophilia A, von Willebrand disease, fibrinogen deficiency (<1-1.5 mg/dl)	1 U contains 20-50 mL	Increases total fibrinogen by 10-15 mg/dL	• Can be stored up to 4-6 hours when thawed· • Contains fibrinogen + factors V, VIII, XIII, von Willebrand factor

Adapted with permission from [11] and [13]. U: unit, Hct: hematocrit, Hb: hemoglobin. *Platelet counts are considered as cells/cubic millimeters. Watch out for acidosis and hypothermia from transfusion of cold blood components.

diagnosis.[5] The obstetrician is immediately involved and needs to take up the patient for uterine repair. A neonatologist needs to be on board to prevent fetal anoxia and its sequelae.

Uterine inversion is a sequela of fundal pressure and excessive umbilical cord traction. The uterus turns inside out and there may be considerable bleeding. Start the basic protocol of managing obstetric hemorrhage (Fig. 135.1) and try to reposition the uterus promptly. If this fails, transfer the patient to the operating room to reposition the uterus under general anesthesia. Nitroglycerin may be tried as an adjunctive measure, initially as 400 mcg/spray sublingually, followed by 20 mcg/IV.[24] Once repositioned, stop all tocolytics and start uterotonic agents like oxytocin or prostaglandins (Fig. 135.1).

ACUTE HYPERTENSIVE DISORDERS IN OBSTETRIC CRITICAL CARE

Preeclampsia is defined as the onset of hypertension after 20 weeks of gestation, along with (1) a constellation of clinical features (edema, visual disturbances, headache, epigastric pain) and/or (2) more than 300 mg of protein in a 24-hour urine sample (>1+ on dipstick test) in a previously normotensive woman.[25,26] A blood pressure of more than 140 mm Hg systolic and/or more than 90 mm Hg diastolic, without clinical features or proteinuria in the same time frame, is known as gestational hypertension; 25% of these can go on to preeclampsia.[26] New onset clinical features or proteinuria in a woman with a) hypertension before 20 weeks b) sudden increase in proteinuria or hypertension, or c) the development of HELLP (hemolysis, elevated liver enzymes and low platelets) syndrome is defined as superimposed preeclampsia.[26] New onset grand mal seizures or coma superimposed on preeclampsia/gestational hypertension is defined as eclampsia.[25,26] Headache, hyperreflexia, clonus and visual signs often precede eclampsia.

If uncontrolled, preeclampsia can progress to severe preeclampsia (Table 135.3A). Uncontrolled severe preeclampsia can lead to complications that are classified as maternal (hypertensive crisis, eclampsia, intracranial hemorrhage, temporary blindness, acute myocardial infarction, congestive heart failure, pulmonary edema, liver failure, renal failure, HELLP syndrome, disseminated intravascular coagulation [DIC]), placental (subchorionic hematoma, placental abruption, recurrent bleed) and fetal (preterm labor, intrauterine growth retardation, oligohydramnios, death).[25] Features of a hypertensive crisis include altered sensorium, focal

TABLE 135.3A: Diagnostic criteria for severe preeclampsia

Symptoms

- Headache
- Visual disturbances
- Epigastric/right upper quadrant pain

Signs

- Blood pressure > 160/110 mm Hg on at least 2 occasions 6 hours apart
- Pulmonary edema
- Oliguria (<400 ml/24 hours)

Laboratory tests

- Proteinuria > 5 grams/24 hours
- Elevated serum creatinine
- Evidence of HELLP (hemolysis, elevated liver enzymes and low platelets) syndrome
- Fetal ultrasound – intrauterine growth retardation

Adapted from [26]

neurological deficits, rales, an audible S3, ascites, ecchymosis and oliguria.[25] The differential diagnoses of severe preeclampsia include placental abruption, amniotic fluid embolism and the complications of intrauterine fetal demize. The differential diagnoses of eclampsia include hypertensive encephalopathy, bleeding arteriovenous malformation, ruptured aneurysms and idiopathic seizure disorder. The absence of retinal hemorrhages and papilledema helps to differentiate eclampsia from the rare hypertensive encephalopathy. Patients with end-organ damage, complications, or a blood pressure of greater than 240/140 need ICU admission.

Management of the patient having a hypertensive emergency in pregnancy involves stabilizing the patient, preventing seizures, controlling the blood pressure and deciding the further management. Ensure airway, breathing, circulation, and place the patient on the lateral side; inform the obstetric team immediately. The maternal well-being is always given precedence; continuous fetal monitoring needs to be started as the mother is stabilizing.[27] The tests to be ordered in severe preeclampsia along with their interpretation are given in Table 135.3B. A tight fluid balance is needed that focuses on restriction (limit to 1 mg/kg/hr) in order to prevent pulmonary edema.[28] If pulmonary edema occurs, give intravenous furosemide and morphine (Furosemide: 20 to 40 mg IV over 2 minutes, followed by a repeat dose 30 minutes later if necessary, up to a maximum dose of 120 mg/hr; Morphine: 2 to 5 mg IV). Closely monitor the urine output; if oliguria is present, but the renal function is normal, diuretics are not essential.[29] Invasive hemodynamic monitoring is helpful in severe renal

TABLE 135.3B: Interpretation of diagnostic tests

Parameter	*Interpretation*
In all patients	
Complete blood count	Hemoconcentration is an indicator of severity
Peripheral smear	For evidence of hemolysis (schistocytes, burr cells)
Platelet count	Platelets <100,000/mm^3 suggests severe preeclampsia; look for HELLP syndrome
Liver function tests	ALT, AST, serum bilirubin elevated in HELLP syndrome
Serum BUN, Creatinine	Creatinine > 1.2 mg/dL + oliguria – suggest severe preeclampsia
Serum uric acid	Values > 5.6 mg/dl suggest severe preeclampsia
Urinalysis and microscopy	Muddy casts suggest acute tubular necrosis
24-hour urine collection for protein and creatinine clearance	Pregnancy-associated hypertension when associated with proteinuria (> 300 mg/24 hours) should be considered preeclampsia unless proven otherwise; high excretion (> 5 g/24 hours) indicates severe preeclampsia
Blood type and antibody screen	Keep the blood bank informed as an emergency vaginal or cesarean delivery may be needed if patient deteriorates
Obstetric ultrasound	For evidence of intrauterine growth retardation
Selective tests	
Serum LDH	Elevated in HELLP syndrome (especially when > 600 IU/L)
Coagulation profile	Elevated PT or aPTT, decreased fibrinogen indicate impending DIC
Uterine artery Doppler velocimetry	Absent or reversed end-diastolic flow indicates severe preeclampsia and possible risk to fetus
	HELLP: hemolysis, elevated liver enzymes and low platelets, DIC: disseminated intravascular coagulation, aPTT: activated partial thromboplastin time. Monitor these tests over time to identify worsening of maternal status, especially during conservative management.

Adapted with permission from Polley et al[30] failure, and refractory hypertension, oliguria and pulmonary edema[26] because central venous pressure (CVP) poorly correlates with the pulmonary arterial wedge pressure in these patients.[29]

Magnesium sulfate ($MgSO_4$) is better than phenytoin or diazepam for preventing/treating eclamptic seizures.[26] It is given through an infusion pump as a 4 to 6 grams loading dose diluted in 100 mL of isotonic fluid over 15 to 20 minutes. This is followed by a continuous infusion of 2 grams/hour. Target serum levels of Mg for prophylaxis are between 4 to 6 mEq/L. EKG changes are seen above 5 mEq/L.[29] $MgSO_4$ is safe in renal insufficiency, but is contraindicated in those with myasthenia gravis. The maintenance dose is only given if (1) Respiration is normal, (2) Oxygen saturation is adequate, (3) Urine output is greater than 20 mL/hr and (4) Patellar reflex is normal.[28] If there is respiratory depression or hyporeflexia (which suggests a Mg level > 10 mEq/L), give 1-gram calcium gluconate IV (10 mL over 10 minutes). If the seizures recur, give any of these: a 2 gram bolus of $MgSO_4$, diazepam (0.1 to 0.3 mg/kg over 60 seconds; maximum dose 30 mg), lorazepam (0.02 to 0.03 mg/kg IV up to a total of 0.1 mg/kg, maximum rate of infusion: 2 mg/min), a single dose of sodium amobarbital 250 mg IV (over 3 to 5 minutes). If seizures are still recurring, the patient may need intubation. $MgSO_4$ is continued for 24 hours following delivery or after the last seizure, whichever is later,[28] or at least 12 hours, after which it may be discontinued if (1) the patient has no headache, visual changes and epigastric pain in that interval, (2) the blood pressure has been kept below 150/100 without antihypertensive medication and (3) the urine output has been over 100 mL/hr for at least 2 hours without medication.[30]

The diastolic blood pressure should be gradually decreased—generally over 30 to 60 minutes—to between 100 to 110 mm Hg, so as to ensure adequate uteroplacental perfusion.[28] A good thumb rule is reducing it by 10 to 20 mm Hg every 10 to 20 minutes.[30] Currently, there is no preferred antihypertensive among hydralazine, labetalol or slow-release nifedipine that has proven better than the other for the management of acute hypertensive emergencies in pregnancy.[31] Some clinicians prefer using labetalol.[25] If none of these works, then nitroprusside, nitroglycerin or prazosin may be used as second line drugs. Characteristics of the most commonly used antihypertensive drugs used in severe preeclampsia are given in Table 135.4. For a more complete discussion, refer to the review article by Vadaeff et al.[25] ACE inhibitors are contraindicated in

TABLE 135.4: Commonly used antihypertensive medications in pregnancy

Drug	*Advantages*	*Disadvantages/Contraindications/Side effects*
Hydralazine IV (Dose: 5-10 mg every 15-20 minutes; Maximum dose – 30 mg)	Onset within 10-20 minutes	• Poorly tolerated compared to others· • Less effective than nifedipine • Can cause reflex tachycardia, hypotension, headaches, flushing, anxiety, vomiting, epigastric pain, fluid retention • Can cause thrombocytopenia, lupus-like syndrome, fetal distress (prolonged infusion) syndrome in neonate • Hypotensive overshoot secondary to volume depletion
Labetalol IV (Dose: 1 mg/kg continuous infusion Bolus – Start with < 20 mg, then increased as 40, 80, 80, 80 and 80 mg q15 min; maximum dose – 300 mg)	• Onset in < 5 minutes· • Reduces myocardial oxygen consumption, no reflex tachycardia nor bradycardia· • Does not influence renal function, end-organ perfusion, cardiac output or fetal heart rate· • Useful in MI, LVF, CHF, atrial fibrillation, cerebrovascular accidents, hypertensive encephalopathy	• Contraindicated in patients with asthma, preexisting myocardial disease, decompensated cardiac failure· • Can potentiate myocardial depression when given with calcium channel blockers· • Side effects include dizziness, nausea, headache, fatigue, bronchoconstriction and hyperglycemia. • Can cause hypotension, hypoglycemia, hypothermia, bradycardia in neonate
Nifedipine (SR) (10 mg capsules orally, repeat q15-30 min; maximum dose – 30 mg)	• Onset in 45-90 min • Increases cardiac index and renal flow· • No effect on end-organ perfusion and fetal heart rate	• Onset of action of SR capsules may be too slow for HT emergencies • May cause neuromuscular blockade/severe hypotension with magnesium sulfate • Side effects include tachycardia, palpitations, headaches, flushing, ankle edema

pregnancy and used only as the last resort, when other medications fail to resolve the hypertensive crisis. Diuretics are also avoided, though they may be continued if they had been started prior to pregnancy.[25] They may have value in patients with renal failure, resistant heart failure or pulmonary edema. They should be considered on a case-by-case basis, e.g. weighing the pros and cons in patients with the already established evidence of uteroplacental insufficiency or intrauterine growth retardation.

While the definitive method to abort the preeclampsia is by delivering the fetus, the physician should also consider the gestation and the maternal and fetal status. If both mother and child are stable, then the pregnancy can be delayed till term by controlling the blood pressure and using seizure prophylaxis. If the gestation has not crossed 34 weeks and the mother is in danger, preparations should be made to induce labor or for a cesarean section, which is mainly done for obstetric reasons. Intramuscular betamethasone should be administered immediately. The delivery should be well-planned and be ideally conducted under optimal circumstances, unless there is evidence of fetal distress (e.g. bradycardia or meconium stained liquor), when it should be prompt. Ergometrine is withheld even if postpartum hemorrhage occurs because it can precipitate hypertensive crisis; use oxytocin instead. Antihypertensive drugs that can be safely given postpartum are methyldopa, hydralazine, ACE inhibitors and magnesium sulfate; beta-blockers are best avoided. Hypertensive disorders still contribute to 30% of maternal mortality in India, and HELLP syndrome (Table 135.5) and pulmonary edema are the most common causes of death in these patients.[32,33]

VENOUS THROMBOEMBOLISM (VTE) IN PREGNANCY

The hypercoagulable state of pregnancy puts patients at a greater risk of deep venous thrombosis (DVT) and pulmonary embolism (PE), which can occur in any trimester of pregnancy and even up to 6 weeks after delivery.[34] An inherited thrombophilia may be unmasked in pregnancy; interestingly, thrombophilias are associated with 50% of the VTE cases in pregnancy.[34] The clinical features of VTE are same as those in nonpregnant patients; however, many of the features, such as leg swelling, dyspnea and tachycardia are normal in pregnancy. Thus, a high suspicion, but judicious objective testing helps to identify these patients. Unless it is contraindicated, treatment with low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH) is advisable in patients who are suspected to have a VTE, at least until the results of the objective testing are available.[35]

Compression ultrasonography is the first test that should be done in pregnant patients with suspected DVT or PE.[34] However, it may miss iliac vein thrombosis, which may be picked up by magnetic resonance direct thrombus imaging (preferable over CT imaging in pregnant patients). The complete algorithm is given in Figure 135.3. A negative D-dimer test does not rule out VTE.[36] Once a VTE is detected, continue heparin. LMWH is now preferred over UFH as the standard treatment, and a twice daily regimen is preferred because of the decreased half-life of heparin in pregnancy, secondary to the increased renal excretion.[34] The dose of LMWH increases with body weight.[34,35] Factor Xa levels are recommended only in morbidly obese or thin patients, and in those with renal insufficiency. A vena caval filter is placed in (1) those whom anticoagulation is contraindicated and (2) in those whom an extensive VTE develops (a) two weeks before delivery or (b) the activated partial thromboplastin time (aPTT) is already in the therapeutic range.[37] For patients in whom heparin is contraindicated, fondaparinux (Category B drug) may be a safe alternative though there is limited knowledge of its safety.[38] Thrombolytics are reserved for those patients having an acute massive PE with hemodynamic compromise. However, if surgery/delivery has occurred within the last 10 days, it is contraindicated, although there have been exceptions to the rule.[39] Surgical/interventional methods are also available—hence, treatment should be individualized. A patient with a massive PE, at term or at a point where the fetus is in distress but has a chance of survival, may need an emergency cesarean section. All pregnant patients with a stable PE will need a temporary vena caval filter once the diagnosis is confirmed.[34] All patients with VTE need compression stockings both antepartum and postpartum.[35]

The last dose of therapeutic LMWH should be given 24 hours before the delivery while that of UFH should be given 6 hours prior to delivery. Follow it by confirming that the aPTT is in the physiological range. LMWH may be resumed 12 hours after delivery/surgery in the absence of bleeding. Warfarin is safe in the postpartum period and should be given for at least 6 weeks, ideally for at least 6 months.[34]

CARDIAC DISEASE IN PREGNANCY

The hemodynamic changes of pregnancy can unmask a hitherto undiagnosed cardiac disease in obstetric

TABLE 135.5: Liver diseases in pregnancy

Disease	*Clinical Features*	*Jaundice*	*Incidence*	*Lab Values*	*Adverse Effects*	*Treatment*	*Comments*
Hyperemesis gravidarum	Nausea, vomiting, dehydration, ketosis (uncommon), no pain usually	Rare, if present – mild	0.3-1.0%, mainly in 1st or 2nd trimester	Bilirubin < 4 mg/dl, ALT <200 IU/L (may rise to 20X normal), decreased phosphate, magnesium, potassium	Low birth weight	Hydration, antiemetics, slowly introduce solids orally; add nutrients like thiamine	• Biochemical abnormalities should normalize as vomiting resolves· • Rule out hyperthyroidism
Intrahepatic cholestasis of pregnancy	Pruritus (esp. of palms and soles) followed by generalized symptoms, no pain	Present in 20-60% of cases 1-4 weeks after pruritus	0.1-0.2%, mainly in 2nd or 3rd trimester	Bilirubin < 6 mg/dl, ALT < 300 IU/L (may rise to 20X normal), fasting serum bile acids > 10 umol/L diagnostic	Stillbirth, premature birth, bleeding, fetal mortality 3.5%	Drug of choice: UDCA; maintain bile acids <40 umol/L; add fat soluble vitamins	• Resolves after delivery; if it does not, consider the familial form that may progress to cirrhosis
Acute fatty liver of pregnancy	Upper abdominal pain, nausea, vomiting, neurologic dysfunction	Common, occurs 1-2 weeks post-onset of symptoms	4.4% of critically ill obstetric patients in an Indian ICU, commonly seen in 3rd trimester	Leukocytosis, ALT < 500 IU/L, increased bilirubin, ammonia and uric acid late in disease, renal dysfunction may be present, DIC in > 75% cases	Maternal mortality in untreated -high; with prompt treatment - <20%; SIDS in neonate	Prompt delivery of fetus should resolve jaundice (within 4 weeks) and DIC; yet may need liver transplant	• Low BMI, multiple gestations, nulliparity increase risk· Hypoglycemia suggests a poor prognosis· Neonatologist essential • Liver dysfunction resolves within 2 weeks of delivery·
Preeclampsia and eclampsia	Upper abdominal pain, edema, HTN, nausea, vomiting, neurologic dysfunction	Late, seen in 5-14% of cases	5-10%, seen in 2nd or 3rd trimester	ALT <500 IU/L (if > 500, consider infarction), proteinuria, DIC in 7% cases	Increased maternal and fetal mortality	Blood pressure control; immediate delivery may be necessary	• Subcapsular hematoma may occur • Hypertension and proteinuria may be absent in 15% cases.
HELLP syndrome (Hemolysis, elevated liver enzymes and low platelets)	Often asymptomatic, in other cases – pain, nausea, vomiting	Late, seen in 5-14% of cases	Only 5-10% of cases have preeclampsia; occurs mainly in 2nd/3rd trimester, but can also occur after delivery	ALT < 500 IU/L, platelets <10000/cu.mm, hemolysis, increased LDH (> 600 IU/L), DIC in 20-40% cases, renal dysfunction may occur; use Swansea criteria for diagnosis[60]	Increased maternal and fetal mortality; CNS dysfunction, bleeding, hepatic rupture	Supportive management; prompt delivery if: 1. > 34 weeks gestation 2. Fetal distress 3. Severe complications	• Increased PT indicates onset of DIC or severe liver injury
Hepatic hematoma	Sudden severe right upper quadrant pain, pyrexia	Generally absent; if present, due to co-morbidity	Rare, seen in 3rd trimester/puerperium	ALT >3000 IU/L, leukocytosis	Can lead to rupture, ARDS, AKI and shock	• Contained – Blood transfusion and supportive measures. • Unstable patient – May need angiographic embolization or invasive hemostatic measures	
Viral hepatitis	Fever, nausea, vomiting, pain	Common	Same as nonpregnant, any trimester	ALT > 500 IU/L, increased bilirubin, DIC rare, viral serologies positive	Hepatitis E can cause FHF and death	Supportive	

Adapted from [58] and [59]. *Other causes of right upper quadrant pain in these patients include biliary tract disease (cholecystitis or choledocholithiasis), drug-induced hepatitis and Budd-Chiari syndrome.* UDCA: ursodeoxycholic acid, ALT: alanine aminotransferase, BMI: body mass index, HTN: hypertension, LDH: lactate dehydrogenase, DIC: disseminated intravascular coagulation, PT: prothrombin time, ARDS: acute respiratory distress syndrome, AKI: acute kidney injury, FHF: fulminant hepatitis failure

Fig. 135.3: Diagnosis and management of venous thromboembolism (VTE) in pregnancy [Adapted with permission from (34)]

patients.[40] Some of the clinical features of cardiac disease overlap with the normal features of pregnancy. However, chest pain, severe breathlessness, orthopnea, paroxysmal nocturnal dyspnea, an irregular pulse, an S_4 heart sound, pulmonary edema or pleural effusions are pathological.[41] Obstetric patients at the highest risk of decompensation are those with NYHA Class III and IV heart failure, cyanosis, Marfan's syndrome, left heart obstruction (severe AS), Eisenmenger's syndrome, an ejection fraction of <40%, severe pulmonary hypertension (pulmonary arterial pressure > 75% of mean arterial pressure), mechanical prosthetic heart valves, and an aortic root diameter > 40 mm.[42,43]

A majority of these cases in Indian ICUs are due to rheumatic heart disease.[4] Management of these patients is similar to nonpregnant patients. The goals are to maintain normal heart rate and rhythm, and an adequate systemic vascular resistance, intravascular volume and venous return. Avoid aortocaval compression, myocardial depression by drugs, and the rise in pulmonary vascular resistance caused by pain, hypoxemia, hypercarbia and acidosis. Carefully monitor the fluid balance. If the symptoms still do not resolve, consider balloon mitral valvuloplasty.[41] Beta-blockers may be used in pregnant patients to treat arrhythmias; however, they can cause intrauterine growth retardation.

Penicillin can be used in these patients as prophylaxis for recurrences. Infective endocarditis prophylaxis is only indicated for complicated vaginal or cesarean delivery in patients with prosthetics valves, previous infective endocarditis, complex congenital heart disease, or valvulopathy in patients with cardiac transplants.[44] In patients with mechanical valves, the decision regarding anticoagulants needs to be taken along with the patient while balancing the risks of warfarin embryopathy with the less than ideal anticoagulant effects of heparin.[40] The american college of chest physicians has guidelines for anticoagulation during pregnancy.[45] Low-dose aspirin is safe and recommended in these patients, unlike in those with venous thromboembolism.[40]

Peripartum cardiomyopathy is a rare complication in pregnancy, but was found in 5.8% of the obstetric patients admitted to an American ICU.[4] It is a diagnosis of exclusion, the criteria being:[46]

1. Congestive heart failure symptoms of an unknown cause.
2. Absence of a preexisting cardiac muscle disorder.
3. Onset of symptoms during the last month of gestation until 5 months postpartum.
4. Left ventricular systolic dysfunction, identified by depressed ejection fraction.

The etiology is unknown; however, maternal age over 30 years, hypertension in pregnancy, multiparity, multiple gestations, use of beta-agonists during pregnancy and a low socioeconomic status increase the risk.[47] Management is similar to cardiac failure in nonpregnant patients. The only difference is that ACE inhibitors, if indicated, should only be started postpartum.[40] 80% of the women recover completely. In patients with refractory heart failure, a left ventricular ejection fraction of <25% and cardiac troponins raised within two weeks of onset predict a poor prognosis, and possibly the need of a transplant.[40,48] In refractory cases, delivery is necessary.

RESPIRATORY DISORDERS IN PREGNANCY

The differential diagnosis of dyspnea in pregnancy includes acute asthma, pulmonary embolism (thrombus, amniotic fluid and air), pneumonia, aspiration pneumonitis and pulmonary edema. A few of these patients may eventually need either noninvasive or invasive ventilation to sustain adequate oxygenation.

The important points in the ventilation of pregnant patients are:[49]

- Use a smaller endotracheal tube (size 6–7 mm) and nasotracheal intubation to reduce trauma to an already edematous and vascular upper airway.
- Place the patient in the left or right lateral position; change sides periodically.
- Do continuous electronic fetal monitoring to identify any signs of distress.
- Indications for neuromuscular relaxation and sedation: High levels of PEEP, hemodynamic instability (use nondepolarizing agents like atracurium, cisatracurium, vecuronium, pancuronium; cisatracurium preferred; alternatively, benzodiazepines or propofol in third trimester); when these agents or opioids are used, inform a neonatologist so that they are ready to resuscitate the fetus if necessary.

Tocolytic-induced pulmonary edema, the most common cause of pulmonary edema in pregnancy, is a noncardiogenic side effect that occurs either immediately after starting high doses of beta-agonists, within 24 hours of discontinuation or within 12 hours postpartum,[50] especially in mothers with multiple gestations, concurrent infection or those who are receiving steroid therapy.[51] Fluid retention in the days preceding the onset can alert the clinician to this complication.[49] It is a Type 1 (hypoxic, hypo/normocapneic) respiratory failure, promptly responds to oxygen, diuretics and discontinuation of medication, and is fortunately associated with very low maternal and fetal mortality.[50]

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism is a rare complication that causes rapid deterioration of the mother's hemodynamic status and in a majority of cases, leads to her death.[52] Most of the cases occur during labor or within 30 minutes of delivery. However, it may occur earlier due to uterine manipulation during trauma or abortion.[53] It is characterized by sudden onset hypotension and cardiorespiratory arrest along with fetal distress (if fetus is still present *in utero*). Soon, the patient develops cyanosis, neurodysfunction and starts bleeding uncontrollably.[52] The physician needs to rule out uterine rupture, sepsis and hemorrhage that present similarly.[53] Amniotic fluid embolism is especially suspected when the results of the coagulation tests are abnormal for the first time within 30 minutes of delivery. The pathogenesis is believed to be due to the activation of inflammatory and coagulation cascades when the amniotic fluid gains access to the systemic circulation, leading to a

- Cricoid pressure to be applied in bag and mask ventilation, and intubation
- Hands to be placed higher on the sternum in chest compressions
- Endotracheal tube diameter to be 0.5–1 mm smaller than that in non-pregnant women
- Do not administer any medication by any IV access placed in the lower extremity
- Disconnect fetal and uterine monitors prior to defibrillation
- Method of delivery: Hysterotomy indicated after 24 weeks, and between 20–24 weeks if there is a likelihood of saving the mother by the procedure.
- Hysterotomy to be ideally done within 5 minutes.

Fig. 135.4: Modification in the guidelines for cardiopulmonary resuscitation in pregnant women

phenomenon that has been compared to anaphylaxis.[54] However, unlike anaphylaxis, initially there is pulmonary vasospasm followed by left heart failure, which eventually leads to the pulmonary edema and shock.

Management is supportive, starting with cardiopulmonary resuscitation[55] (Fig. 135.4) followed by stabilizing the patient's ventilation, circulation, and preventing the postpartum complications associated with coagulopathy, especially postpartum hemorrhage. If the fetus has not been delivered, emergency cesarean section should be considered.[52] Nearly three out of five mothers die, often within five days. Out of the survivors, nearly half of the mothers have permanent neurodeficit.[53,54]

A differential diagnosis of amniotic fluid embolism is air embolism, which presents after either delivery or invasive procedures. While the clinical features are similar, a mill-wheel murmur over the chest can alert the physician to this diagnosis. Management should be prompt, involving placing the patient in left lateral position and administering 100% oxygen to shrink the volume of air by driving the nitrogen out of it.[56] The physician should remain alert for pulmonary edema that may develop a few hours later, if the patient survives.

LIVER DYSFUNCTION IN PREGNANCY

Jaundice is the presenting feature in around one-fifth of obstetric ICU admissions, and hepatic dysfunction is seen in nearly 40% of critically ill obstetric patients.[4] Liver function tests need to be interpreted considering the changes associated with pregnancy—however, any elevation of aminotransferases and bilirubin during pregnancy is always pathological (Table 135.6).[57,58] The distinguishing features of the different causes of liver dysfunction are given in Table 135.5.[58-60] It is important to distinguish acute viral hepatitis from pregnancy-associated acute liver disease (PAALD), as the management of the former is often supportive. Generally, hypertension, acute-onset ascites, encephalopathy and oliguria, high serum creatinine and thrombocytopenia favor PAALD over viral hepatitis (which is associated with extremely high (>10X) transaminases).[61]

TABLE 135.6: Pregnancy and alterations in liver function tests

Parameter	*Changes in pregnancy*
Serum ALT, AST	Within normal range; can rise after delivery
Serum LDH	Within normal range
Alkaline phosphatase	Increases to 2-4X normal (bone and placental)
Serum GGT	Normal to low
Serum bilirubin	Normal to low
Serum bile acids	Increase by 200-300% of non-pregnant values
Prothrombin time, APTT	Within normal range
Serum fibrinogen	Increases by 50% from 2nd trimester of pregnancy
Serum albumin	Decreases by 10-60%
Serum uric acid	Decreases
Serum cholesterol	Increases often up to 2X
Serum alpha-fetoprotein	Increases

Adapted from [57] and [59]. ALT: alanine aminotransferase, AST: aspartate aminotransferase, LDH: lactate dehydrogenase, GGT: gamma glutamyltransferase, APTT: activated partial thromboplastin time

RENAL DYSFUNCTION IN PREGNANCY

Renal dysfunction is seen in 35 to 50% of critically ill obstetric patients.[4] Pregnancy-related acute kidney injury (PR-AKI), while ill-defined, contributes up to a fifth of all AKI cases.[62] While patients with chronic mild renal dysfunction (estimated GFR > 60 ml/min/1.73m^2) remain stable with minimal effect on either pregnancy or renal function, those with moderate-severe renal failure are prone to worsening of renal function and complications of pregnancy.[63] The hemodynamic changes in pregnancy affect renal function, and thus the normal values tend to change with the trimester.[63] In this context, a proteinuria of < 300 mg/24 hours is considered normal, as is a respiratory alkalosis (PCO_2 of up to 10 mm Hg below baseline) and a compensatory metabolic acidosis (HCO_3 = 18-20 mm Hg).[62] However, what are considered as upper normal values of BUN and creatinine in nonpregnant patients, are often pathological in pregnancy due to the physiological hemodilution. Generally, a serum creatinine of

> 0.8 mg/dL in these patients should alert the physician to the diagnosis of renal failure.[64]

The classification of renal failure into prerenal, renal and postrenal AKI and the initial workup is similar to nonpregnant patients. Apart from the usual causes, specific etiologies of PR-AKI can be grouped into hypertensive and thrombotic microangiopathies (preeclampsia/HELLP syndrome, acute fatty liver of pregnancy, amniotic fluid embolism, TTP/HUS, postpartum idiopathic AKI), infection (pyelonephritis, sepsis), volume depletion (obstetric hemorrhage, hyperemesis gravidarum) and obstruction (gravid uterus, stone).[62] The most common cause of AKI in pregnancy is preeclampsia; however, this is usually the case only along with another insult like hemorrhage, or HELLP.[64] The role of biopsy in PR-AKI is mainly to find an alternative diagnosis to preeclampsia, in order to avoid the delivery and iatrogenic prematurity, if unnecessary.[62] Hence, the physician should consider the gestational period and the risk of complications, such as perirenal hematoma and gross hematuria (which are higher than in nonpregnant patients) when deciding whether to biopsy.

Management is aimed at treating the underlying cause, preventing complications and supporting the renal function until recovery.[62] While the etiological factors are being corrected, accurate fluid management is essential to ensure adequate renal perfusion. Concurrent medications (e.g. magnesium sulfate) need to be renally dosed. While there is no role of dopamine currently in PR-AKI, judicious use of diuretics is restricted to the cases of volume overload, and that too only when utero-placental perfusion can be frequently assessed.[62] Furosemide and mannitol (Class B) are preferred over thiazides (Class C).[64] Management of complications, such as hyperkalemia, metabolic acidosis and anemia is similar; however, erythropoietin can worsen hypertension[65] and may also require higher dosing.[62] The indications for renal replacement therapy are similar to nonpregnant patients, and early-onset and continuous therapy is considered beneficial (though a randomized control trial is missing, and the exact threshold is undetermined). Increasing the number of dialysis hours per week (over the threshold intervention of 20 hours/week) in order to keep the predialysis threshold of BUN < 60–100 mg/dl is associated with an improvement in fetal birth weight and trends towards improved survival.[62] The physician should prevent sudden fluctuations in hemodynamic status, increase supplementation of vitamins and folate that are removed with dialysis and monitor for preterm labor.

Hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) can occur anytime during pregnancy or postpartum, and can mimic preeclampsia/HELLP syndrome with AKI.[62] Fever, purpura and neurological symptoms point the diagnosis towards TTP, as compared to HUS, which predominantly presents as hemolytic anemia and renal failure. vWF (von Willebrand Factor) multimers can help to differentiate the condition from preeclampsia, because coagulation studies are normal in both disorders. AKI occurs in two-thirds of these patients, and many of them have persistent renal insufficiency, hypertension and often long-term neurologic dysfunction. Fetal consequences include intrauterine growth retardation, fetal distress and death. Management is supportive along with plasmapheresis as the first-line of management, with steroids useful in only 25% of the cases. Unlike preeclampsia, delivery is not beneficial. This helps to differentiate the cause of AKI postpartum in those deteriorating patients who were initially labeled as "AKI secondary to pre-eclampsia".[66] When a patient with similar clinical features has no clear-cut diagnosis, he/she is labeled as "postpartum AKI." The pathogenesis of the condition is similar to other thrombotic microangiopathies, and the management is similar to that of HUS/TTP.[62]

INFECTION IN PREGNANCY

Up to 20% of all maternal deaths can be due to infection. Sepsis is the most common infectious cause of admission in a critically ill obstetric patient.[33] While common causes include pelvic, respiratory and urinary tract infections, patients in the developing countries face an additional threat from viral hepatitis, malaria, leptospirosis, dengue, military tuberculosis and tetanus.[33] A description of different infections specific to pregnancy is given in Table 135.7. Other infections, which are also seen in nonpregnant women, are covered in other chapters.[67-70]

A cesarean section is the most common risk factor for maternal sepsis.[67] The initial source of infection is often polymicrobial, but the predominant organism involved is *Escherichia coli*. The diagnosis and treatment in pregnancy is similar to nonpregnant patients, in line with the Surviving Sepsis guidelines, which have been covered in detail in previous chapters. However, there are certain salient features regarding the management of sepsis in pregnancy.

Diagnosis

- The initial presentation may be nonspecific, and a high index of suspicion is needed. Fever and

TABLE 135.7: Infectious complications in pregnancy

Disease	*Clinical Features*	*Management*	*Comments*
Chorioamnionitis (MC organisms: *E. coli*, Group B *Streptococcus)*	Fever > 100.4F, leukocytosis, tachycardia (maternal/fetal), uterine tenderness, foul vaginal discharge	• Diagnosis primarily clinical; do a sepsis screen • Induce delivery if patient not yet in labor • Start ampicillin 2 g IV q6h + Gentamicin 1.5 mg/kg IV q8h (check renal function) • Clindamycin (900 mg) at time of cord clamping/cesarean section • Acetaminophen for pyrexia	• Be aware of preterm/prolonged labor in all cases • Bacteremia in 5-10% • Fetus may develop neurologic damage despite antibiotic use
Endomyometritis (Organisms- anaerobes, streptococci, gonococci, Chlamydia, Mycoplasma, Gardnerella)	Often presents 24 hours after delivery with similar features as chorioamnionitis + subinvoluted, tender uterus and cervical motion tenderness with or without lochia	• Do endocervical + blood cultures with routine sepsis screen; while false positives may occur, definitely be alert for Group A streptococci • Assume polymicrobial infection (Clindamycin 900 mg IV q8h + gentamicin 5 mg/kg q24h) • Continue for 48h until patient afebrile and has negative blood cultures • If infection spreads to the parametrium and is uncontrolled, hysterectomy may be needed	• Risk factors: Operative interventions, PPH, retained POC, chorioamnionitis • Spiking fever despite antibiotics: consider pelvic abscess; persistent low grade fever: pelvic thrombophlebitis or noninfectious causes • Can spread locally and later generalize → septic shock
Septic abortion (polymicrobial)	Fever, lower abdominal pain and vaginal bleeding in any trimester	• Start empiric therapy [Penicillin 5 MU IV q6h + gentamicin 2 mg/kg IV loading dose (adjust appropriately) + clindamycin 900 mg IV q8h] • Do an upright abdominal X-ray to rule out perforation, foreign bodies and gas in tissues • Uterus may need evacuation – send contents for gram stain and culture • Crepitus ± perforation → surgical exploration	• Cresol, phenol used as abortifacients lead to faster multiorgan dysfunction • Watch out for Clostridial infection, especially those without immunization may suffer from tetanus
Septic thrombophlebitis	Persistent fever, and non-colicky, constant lower-abdominal and flank pain ± radiation; rope-like mass palpable on exam	• Diagnosis confirmed with CT or MRI • Treat with antibiotics • Add anticoagulation (heparin for 5-7 days) with target aPTT of 1.5-2.5 × normal • If thrombus extends into iliac veins or leads to pulmonary embolus β oral anticoagulation	• Common in those who have undergone cesarean section
Necrotizing fasciitis (polymicrobial; MC organisms - *S. aureus*, Group A streptococci	Initially asymptomatic. Swelling, erythema, discoloration, brown discharge. Pain out of proportion to physical findings	• Antimicrobial regimen described for septic abortion + urgent, wide surgical debridement	• Complicates both vaginal and cesarean deliveries- Can rapidly progress to septic shock • Without surgical intervention, mortality is extremely high

MC: most common, PPH: postpartum hemorrhage, POC: products of conception, aPTT: activated partial thromboplastin time. Other common infections in pregnancy are acute pyelonephritis, acute pneumonia, viral hepatitis and malaria. The management of these infections has been covered in detail in other chapters of this book.

leukocytosis or bands on a peripheral smear in a pregnant patient should prompt a search for infection. Incidentally, fever may be absent.
- The localization of infection, when not obvious, should start from genital tract. A thorough clinical examination, followed by ultrasound or MRI is useful.
- The septic screen should include specimens from the cervix, urine and placenta if possible, especially if the blood cultures are negative and the focus is unknown.
- A decrease in blood pressure in the left lateral position, an increase in capillary refill time, change in baseline variability in fetal heart rate and/or late decelerations on the electronic fetal monitor are all signs of impending severe sepsis.

Resuscitation

- The patient should be kept in the left/right lateral position during resuscitation.
- The observed mortality rate in pregnant septic patients is significantly lower as compared to their nonpregnant counterparts. Hence, prompt resuscitation of the mother can often stabilize both the mother and the fetus (which may be in distress). Operative interventions are considered as the last resort.[67]

Breathing

- Unresolving maternal or fetal hypoxia may require mechanical ventilation.
- If permissive hypercapnia is used, ensure that there is no fetal acidosis.

Circulation

The central venous pressure is a poor indicator of the fluid balance and cardiac function in pregnancy. Hence, a pulmonary artery catheter may be necessary in a subset of these patients who are at an increased risk of fluid overload.

Monitoring

- Pregnant patients are at an increased risk of multiorgan dysfunction. The distributive shock of sepsis superimposed on the lower vascular tone predisposes them to acute kidney injury. The increased permeability and lower oncotic pressure predisposes them to pulmonary edema. Their hypercoagulability predisposes them to DIC. Hence, they should be closely monitored.
- The mode of delivery depends on the maternal and fetal condition. If delivery is essential between 24 and 34 weeks of gestation, maternal corticosteroids should be given to promote fetal lung maturity.

Prognosis

The observed mortality in pregnant septic patients is approximately 3%. Fetal survival is good, in spite of severe sepsis in the mother.[67]

In summary, while the management of critically ill obstetric patients is a challenge, the intensivist can help to improve maternal and fetal survival through the following principles:
- Giving precedence to the well-being of the mother over that of the fetus.
- Correctly identifying the conditions that will improve with interventions, such as the induction of delivery and/or operative intervention (e.g. severe preeclampsia), as compared to those that can be managed supportively (e.g. acute viral hepatitis).
- Ensuring a multidisciplinary coordination right from the start between the intensivist, obstetrician, anesthesiologist, neonatologist and subspecialist (as required).

Cardiac Emergencies in the Intensive Care Unit: Cardiac Arrhythmias

Mohamed S Rahman, M Eyman Mortada

INTRODUCTION

Patients in the intensive care unit (ICU) are prone to severe and dramatic swings in fluid and electrolyte balance, cardiac ischemia, hypoxia, catecholamine excess and exposure to cardiotoxic drugs. These situations are a crucible for cardiac arrhythmias. In the current era, sustained arrhythmia in the general ICU is around 8% for supraventricular and ventricular arrhythmias; and 2% for conduction abnormalities.[1] The presence of arrhythmias in the ICU is associated with increased mortality.[2]

Although the most common arrhythmias in ICU patients are supraventricular tachycardias, the ominous specter of ventricular arrhythmia is justifiably the most alarming. From a management perspective, arrhythmias in the ICU can be classified as bradyarrhythmias (heart rate <60), tachyarrhythmias (heart rate >100) and ectopic beats.

PREMATURE VENTRICULAR COMPLEXES (PVCS) (FIG. 136.1)

Premature ectopic QRS complexes arising from the ventricular myocardium – are usually the result of hyper-catecholaminergic states and are relatively benign. They are usually asymptomatic, but occasionally can cause palpitations or neck/chest discomfort. Isolated PVCs do not merit further workup or intervention. However, "multifocal" or polymorphic PVCs, couplets, bigeminy, trigeminy and quadrigeminy may produce more dramatic symptoms. If hemodynamically unstable PVCs persist after the correction of electrolytes and treatment of ischemia, the drug of choice for suppression is intravenous (IV) lidocaine, however, if it fails, intravenous procainamide can be used acutely. Amiodarone and Class Ic drugs are useful for long-term oral maintenance. However, Class Ic drugs (flecainide and moricizine) should not be used after myocardial infarction increase the mortality rate.[3]

ACCELERATED IDIOVENTRICULAR RHYTHM

Accelerated idioventricular rhythm (AIVR) (Fig. 136.2) is usually transient and due to the acceleration of ventricular ectopic focus (automaticity). Accelerated idioventricular rhythms is often seen in the setting of myocardial revascularization, postresuscitation, and occasionally, with digitalis toxicity. This is a benign rhythm and should not be suppressed, as the AIVR is often a back-up rhythm. However, if AIVR is too rapid and producing symptoms or hemodynamic instability, or if it degenerates into ventricular tachycardia (VT) or ventricular fibrillation (VF), it may deserve treatment. Accelerating the sinus rhythm with atropine or pacing may be adequate to suppress the AIVR.

Accelerated idioventricular rhythm needs to be differentiated from sinus rhythm with widening of QRS due to electrolyte imbalance. In hyperkalemia (Figs 136.3A and B), initially peaked tall T waves occur, followed by progressive slowing in conduction through the myocardium with prolongation of the PR interval and the widening of QRS duration. Ultimately, the QRS widens into a "sine wave" and, lastly, a flat line. In hypokalemia, ST depression and decreased amplitude of T wave, as well

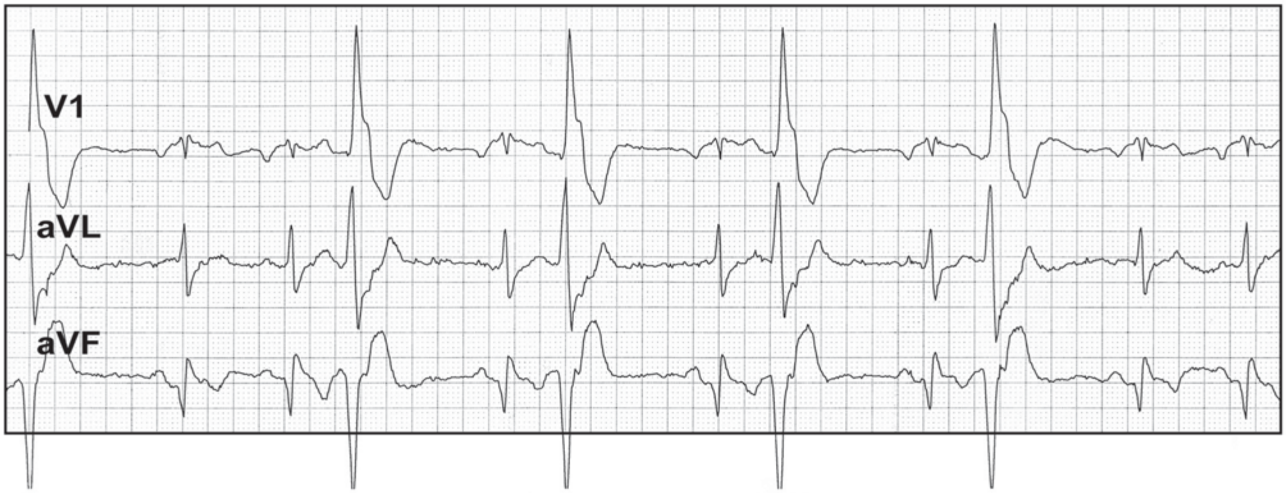

Fig. 136.1: Premature ventricular complexes (PVCs). PVCs occur initially after every two sinus beats (trigeminy), followed by bigeminy. Note the alternating sinus beats and wide (>120 ms) bizarre QRS complexes, which are followed by a compensatory pause. This patient has severe cardiomyopathy and a history of ventricular tachycardia

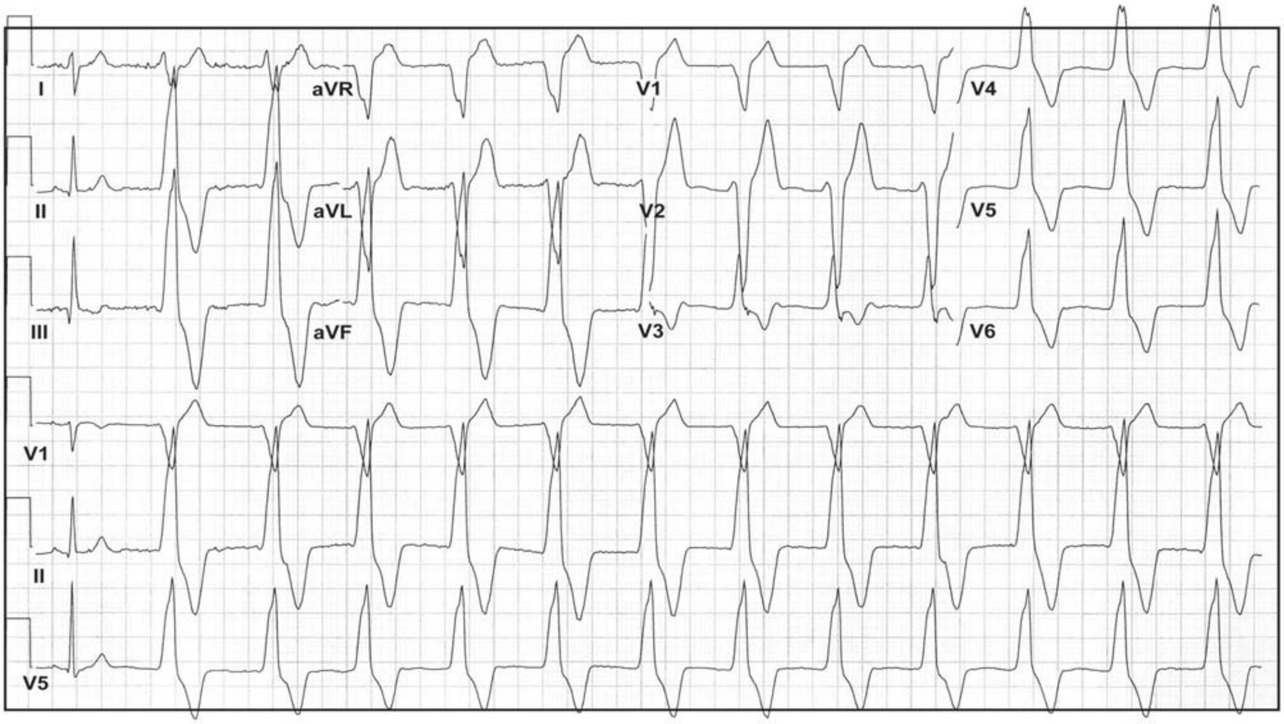

Fig. 136.2: Accelerated idioventricular rhythm (AIVR). 12-lead electrocardiogram (ECG) of AIVR, which is a wide QRS complex ventricular rhythm at a rate of 60-100 bpm. In this ECG, it is associated with atrioventricular (AV) dissociation

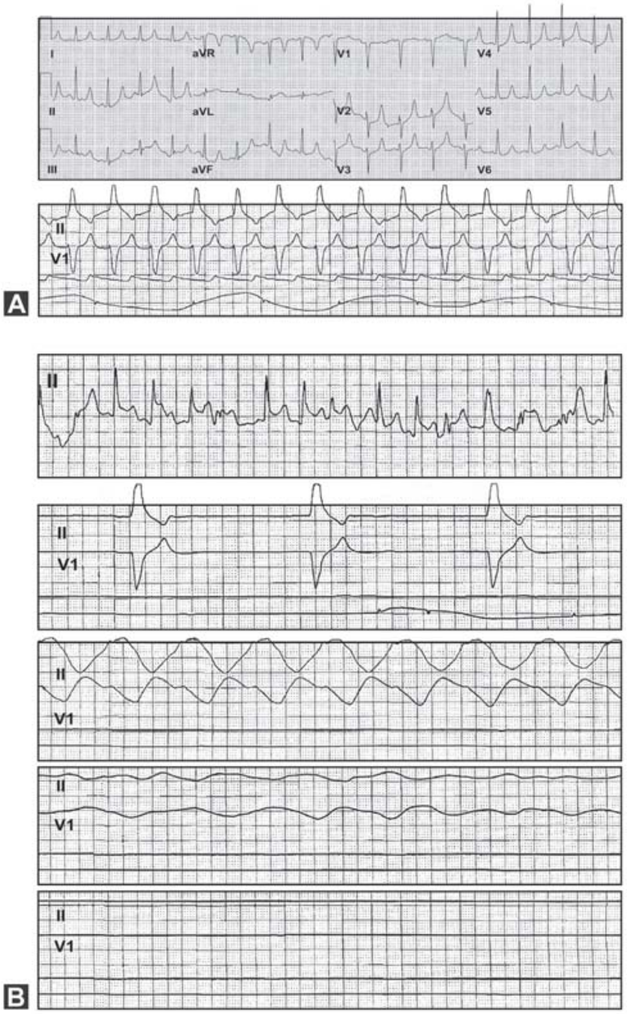


Figs 136.3A and B: Hyperkalemia. Panel A: 12-lead ECG with peaked T waves characteristic of hyperkalemia. Panel B: In the same patient, note the progression of changes on ECG with peaked T waves, followed by prolongation of PR interval and widening of the QRS complexes and ST-T changes resembling acute myocardial infarction, further degeneration to sine wave, and ending in asystole during profound hyperkalemia and severe acidosis due to acute renal failure. Acute hyperkalemia should be addressed by emergent hemodialysis

as U wave in V4-6, may progress to wider QRS and markedly depressed ST with T-wave inversion.

WIDE COMPLEX TACHYCARDIA

A wide complex (QRS >120 ms) tachycardia (WCT) (heart rate >100 beats/min) can be broadly classified as polymorphic when the QRS complex appearance varies from beat to beat and monomorphic when the beat-to-beat QRS complex appearance is identical (Table 136.1). It is crucial to exclude artifact.

Artifact

When examining the rhythm strip, it is essential to evaluate all available leads. Artifact (Figs 136.4A and B) might be present in some leads and not others; hence, the presence of normal rhythm in one lead will exclude WCT. If not, careful review of noisy artifact can reveal regular notches at the same rate as the preceding or continuous rhythm of the patient. Other clues may include an arterial pulse wave tracing that corresponds to the underlying rhythm.

Polymorphic WCT

Polymorphic WCT is almost always ventricular in origin when artifact is excluded — polymorphic ventricular tachycardia (PMVT). Torsades de pointes (TdP) is PMVT due to prolonged QT (Figs 136.5A and B). Atrial fibrillation (AF) in the presence of an accessory pathway may mimic PMVT (Fig. 136.6).

There are five major causes of PMVT:

1. The most important cause in the ICU is myocardial ischemia/infarction (MI);
2. Electrolyte abnormalities (e.g. hypokalemia, hypomagnesemia);
3. Profound bradycardia due to sick sinus node, atrioventricular (AV) nodal block or from medications, such as digoxin, calcium channel blockers or beta blockers;
4. Prolonged QT interval due to medication,[4] electrolyte abnormalities or channelopathies (e.g. long QT syndrome);
5. Idiopathic PMVT.

It is prudent to take steps to avoid TdP/PMVT in the ICU, and recommendations to achieve this are outlined in Table 136.2.

Polymorphic ventricular tachycardia is a rapid, hemodynamically unstable rhythm, which needs electrical cardioversion when persistent. Additional measures include withdrawal of any offending medications, IV magnesium (even when serum magnesium level is "normal"), urgent angiography and angioplasty if myocardial ischemia is suspected or cannot be excluded, temporary pacing or medications to alleviate bradycardia and correction of electrolyte abnormalities. For acute suppression of PMVT, IV lidocaine and oral mexilitine can be used, especially in patients with myocardial ischemia or long QT interval.[6]

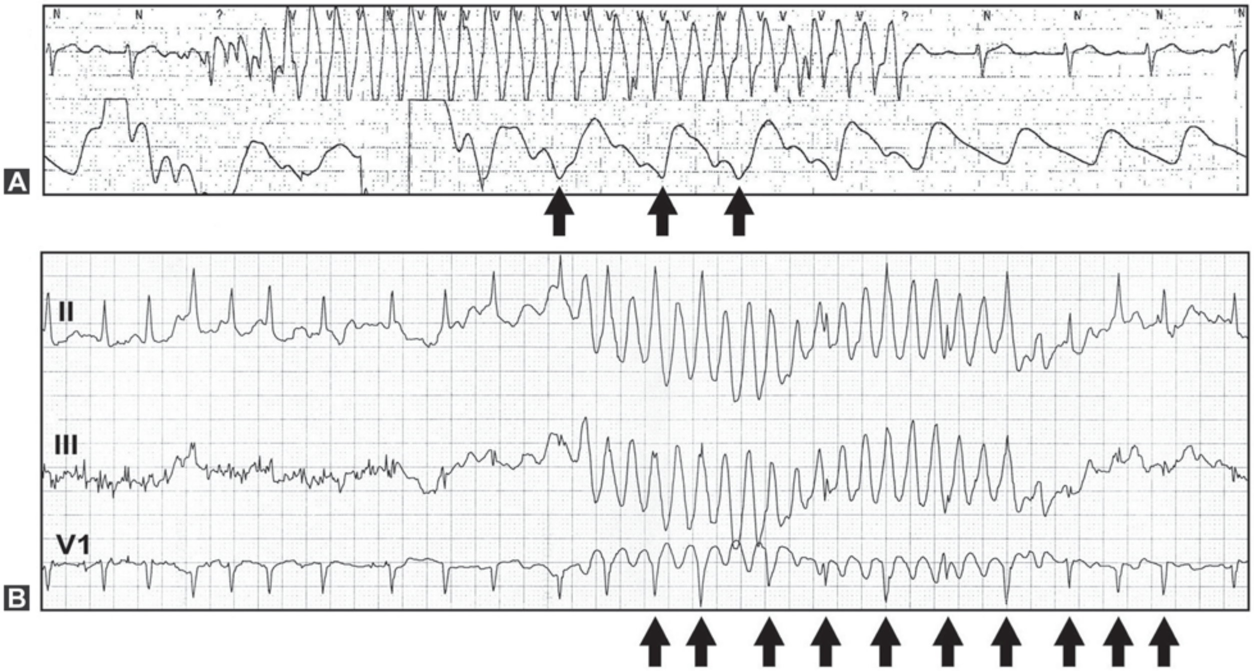
It is crucial to recognize the presence of an accessory pathway (AP) with atrial fibrillation, which produces WCT with irregularity of the QRS morphology and intervals. In this scenario, AV-nodal blocker agents are contraindicated. If they are given, the conduction over

TABLE 136.1: Classification and definition of different ventricular arrhythmias by clinical presentation, ECG features and underlying disease conditions

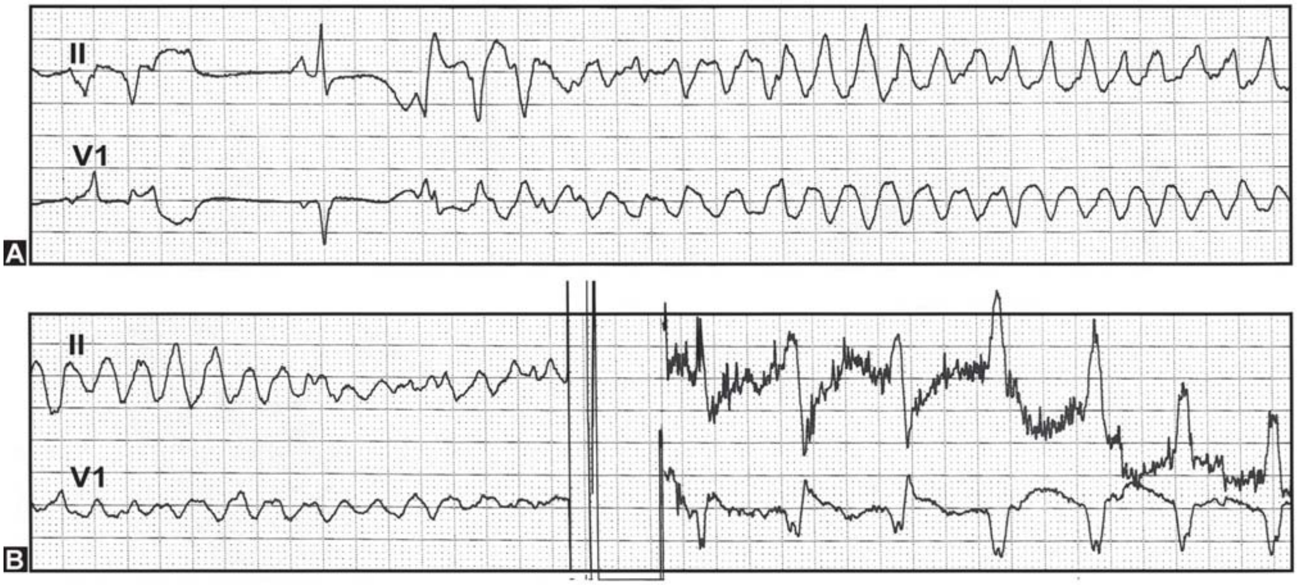
Classification by Clinical Presentation		
Hemodynamically stable	Asymptomatic	The absence of symptoms that could result from an arrhythmia.
	Minimal symptoms	Patient reports palpitations felt in either the chest, throat or neck as described by the following: • Heartbeat sensations that feel like pounding or racing • An unpleasant awareness of heartbeat • Feeling skipped beats or a pause
Hemodynamically unstable	Presyncope	Patient reports presyncope as described by the following: • Dizziness • Lightheadedness • Feeling faint • Graying out
	Syncope	Sudden loss of consciousness with the loss of postural tone, not related to anesthesia, with spontaneous recovery as reported by the patient or observer. Patient may experience syncope when supine.
	Sudden cardiac death	Death from an unexpected circulatory arrest, usually due to a cardiac arrhythmia occurring within an hour of the onset of symptoms.
	Sudden cardiac arrest	Death from an unexpected circulatory arrest, usually due to a cardiac arrhythmia occurring within an hour of the onset of symptoms in whom medical intervention (e.g. defibrillation) reverses the event.
Classification by Electrocardiography		
Non-sustained VT		Three or more beats in duration, terminating spontaneously in less than 30 seconds. VT is a cardiac arrhythmia of three or more consecutive complexes in duration emanating from the ventricles at a rate greater than 100 bpm (cycle length less than 600 ms).
	Monomorphic	Nonsustained VT with a single QRS morphology.
	Polymorphic	Nonsustained VT with a changing QRS morphology at cycle length between 600 and 180 ms.
Sustained VT		VT greater than 30 s in duration and/or requiring termination due to hemodynamic compromise in less than 30 seconds.
	Monomorphic	Sustained VT with a stable single QRS morphology.
	Polymorphic	Sustained VT with a changing or multiform QRS morphology at cycle length between 600 and 180 ms.
Bundle branch re-entrant		VT due to reentry involving the His-Purkinje system, usually with LBBB morphology, this usually occurs in the setting of cardiomyopathy.
Bidirectional VT		VT with a beat-to-beat alternans in the QRS frontal plane axis, often associated with digitalis toxicity.
Torsades de Pointes		Characterized by VT associated with a long QT or QTc and electrocardiography characterized by twisting of the peaks of the QRS complexes around the isoelectric line during the arrhythmia: • "Typical", initiated following "short-long-shot" coupling intervals • Short coupled variant initiated by normal-short coupling
Ventricular flutter		A regular (cycle variability 30 ms or less) ventricular arrhythmia approximately 300 bpm (cycle length 200 ms) with a monomorphic appearance; no isoelectric interval between successive QRS complexes.
Ventricular fibrillation		Rapid, usually more than 300 bpm/200 ms (cycle length 180 ms or less), grossly irregular ventricular rhythm with marked variability in QRS cycle length, morphology and amplitude.
Classification by Disease Entity		
Chronic coronary heart disease		
Heart failure		
Congenital heart disease		
Neurological disorders		
Structurally normal hearts		
Sudden infant death syndrome		
Cardiomyopathies		
Dilated cardiomyopathy		
Hypertrophic cardiomyopathy		
Arrhythmogenic right ventricular cardiomyopathy		

Abbreviations: LBBB = left bundle branch block; VT = ventricular tachycardia.

(From Zipes et al. ACC/AHA/ESC 2006 Guidelines for the Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Death: A report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines. J Am Coll Cardiol. 2006; 48:e247-e346. Reproduced with permission from Elsevier)



Figs 136.4A and B: Artifact. It can be difficult to differentiate artifact from real arrhythmia. Clues include regular pulse wave curves on arterial line tracing during the "tachycardia," as in Panel A. Panel B: Artifact is often noted in one lead while other leads may reveal the underlying rhythm. In the third lead, note the irregular but clear QRS complexes shown by the arrows and corresponding sharp notches in the bizarre artifactual tracings resembling ventricular tachycardia in the upper two leads



Figs 136.5A and B: Torsades de pointes (TdP). Panel A: An ECG tracing of TdP with prolonged QT interval. Notice typical beat-to-beat change in QRS configuration and axis where there is a gradual transition of QRS complex from negative to positive complex relative to baseline. Panel B: Following direct current shock, spontaneous rhythm is restored

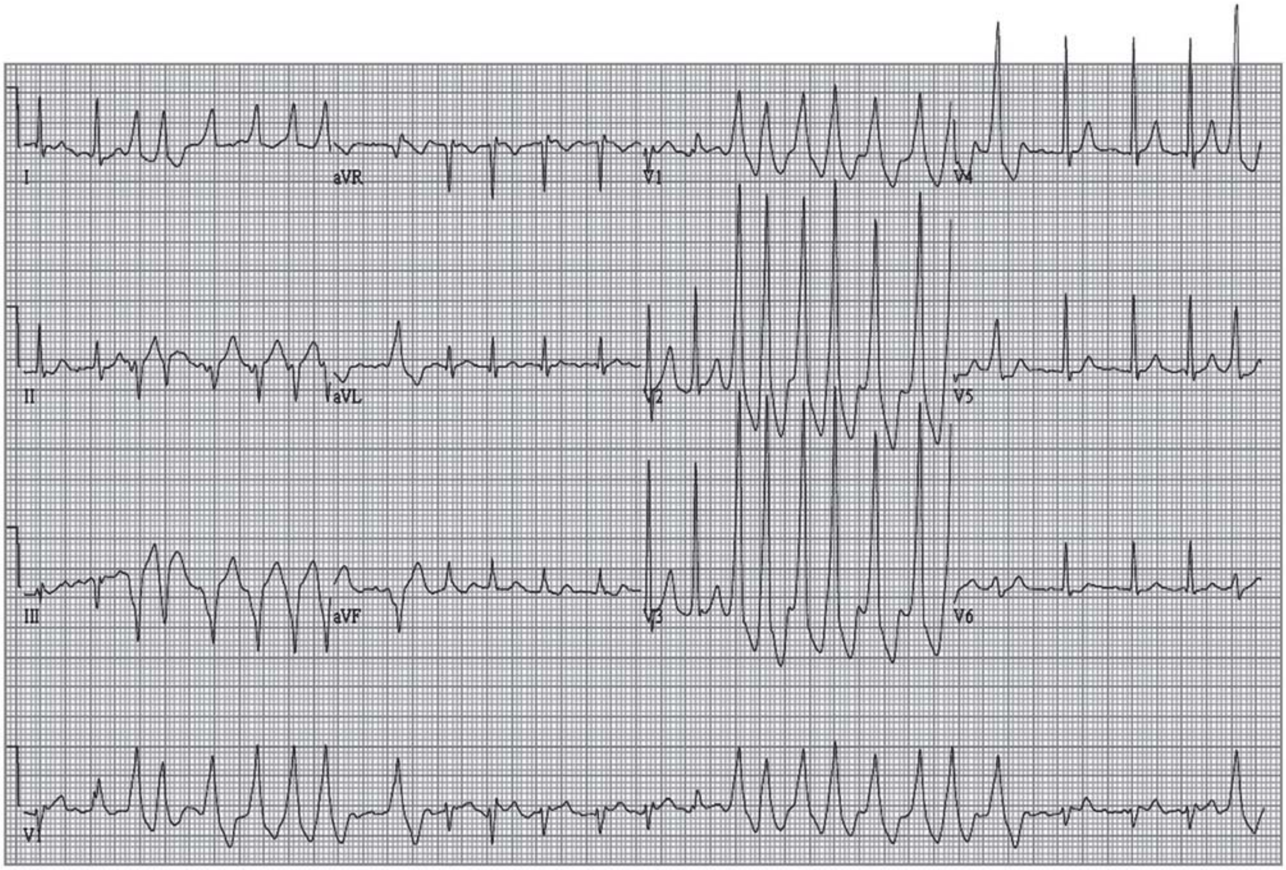


Fig. 136.6: Atrial fibrillation with Wolff-Parkinson-White syndrome. Irregularly irregular wide complex tachycardia. Impulses from the atria are conducted to the ventricles via either the atrioventricular (AV) node and accessory pathway, producing a broad fusion complex, or just the AV node, producing a narrow complex (without a delta wave), or just the accessory pathway, producing a very broad "pure" delta wave. People who develop this rhythm and have very short R-R intervals are at higher risk for ventricular fibrillation.

the AP will be accelerated and ventricular fibrillation may be provoked. The drugs of choice are procainamide or amiodarone (suppressing AV node and AP).

Monomorphic WCT

Monomorphic WCT can be due to VT, pre-excited tachycardia [antidromic atrioventricular re-entry tachycardia (AVRT) or supraventricular tachycardia (SVT) with bystander AP], SVT with aberrant conduction, SVT with preexisting bundle branch block and, rarely, pacemaker-mediated tachycardia (PMT) in which the pacemaker tracks either a sensed atrial tachyarrhythmia or a retrograde atrial activity in an endless loop. Pacemaker-mediated tachycardia is recognized by observing the pacing spike at the initiation of the QRS and by interrogating the pacemaker and can be abolished by special reprogram maneuvers.

It is essential to differentiate VT, which is a dangerous arrhythmia, from SVT in WCT. Patients with structural heart disease have more than a 95% chance of having VT, especially those with prior myocardial infarction (98%). Electrocardiogram (ECG) features, suggestive of VT as a cause for a WCT, include:

- Atrioventricular dissociation;
- QRS > 140 ms with right bundle branch block or >160 ms with left bundle branch block;
- Positive QRS concordance;
- Extreme left-axis deviation (-90° to 180°) "north-west axis"
- Left bundle right-axis configuration [right ventricular outflow tract (RVOT) VT];
- Different QRS during tachycardia than baseline.[6]

Sustained Monomorphic Ventricular Tachycardia

Among adults with in-hospital cardiac arrest, survival was worse when ventricular arrhythmia was the first documented rhythm (Figs 136.7A and B), compared to when asystole or pulseless electrical activity (PEA) was

TABLE 136.2: Approach to ventricular tachycardias in the adult ICU patient*

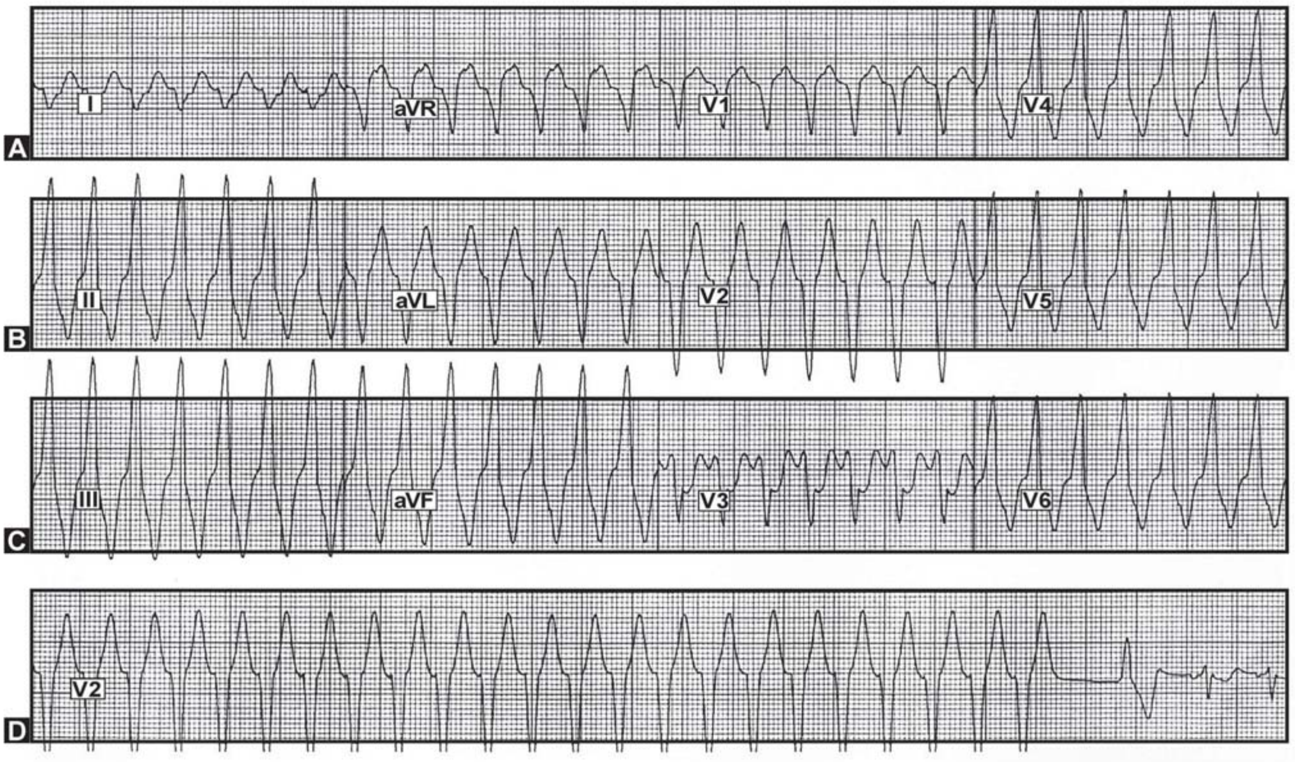
Condition	*Treatment*	
No pulse – pulseless ventricular tachycardia	Synchronized cardioversion	
Unstable ventricular tachycardia	Synchronized cardioversion	
Stable ventricular tachycardia	Assess QRS complex morphology	
Stable Monomorphic VT		
Normal cardiac function	**Medications: First line** Procainamide (min 20-30 mg to max total 17 mg/kg) Sotalol **Medications: Second line** Amiodarone (150 mg IV bolus over 10 min) Lidocaine (0.5-0.75 mg/kg IV push) **Synchronized cardioversion**	
Reduced LVEF	**Medications** Amiodarone (150 mg IV bolus over 10 min) Lidocaine (0.5-0.75 mg/kg IV push) **Synchronized cardioversion** **EP Study** **ICD**	
Stable Polymorphic VT		
Normal baseline QT interval	**Correct electrolytes** **Rule out myocardial ischemia** **Correct profound bradycardia** **Medications** Beta blocker Lidocaine (0.5-0.75 mg/kg IV push) Procainamide (20-30 mg/min to max total 17 mg/kg) Amiodarone (150 mg IV bolus over 10 min) Sotalol	
Synchronized cardioversion		
Prolonged baseline QT interval (torsades de pointes)	Acquired QT prolongation	**Stop offending agent** **Correct electrolyte disturbance** Potassium repletion to 4.5-5 mmol/L **Medications** Magnesium sulfate **Cardiac pacing**
	Congenital QT prolongation	**Beta blockers** **Pacing** **ICD**

*The first priority is hemodynamic stability. Stable VT can be addressed based on QRS morphology as outlined.

Abbreviations: EP = Electrophysiology; ICD = Implantable cardioverter defibrillator; ICU = Intensive care unit; IV = Intravenous; LVEF = Left ventricular ejection fraction; VT = Ventricular tachycardia.

the first documented rhythm.[7,8] Survival after in-hospital cardiac arrest is almost exclusively dependent on the speed of defibrillation with an approximately 10% decrease in survival for every 1-minute delay in defibrillation.[9] Regardless of cause, the treatment of unstable WCT is immediate and effective electrical cardioversion.

In hemodynamically stable sustained monomorphic ventricular tachycardia (MMVT), antiarrhythmic medications can be used for cardioversion as outlined in Table 136.2. Further, an electrophysiology consultation for possible implantable cardioverter defibrillator (ICD) placement or an electrophysiology study (EPS) with ablation [e.g. idiopathic left VT, RVOT VT (left bundle +



Figs 136.7A to D: Monomorphic ventricular tachycardia (MMVT). 12-lead electrocardiogram of MMVT. QRS complex is wide (200 ms), with right axis (+120°) and marked slurring of 'S' wave on V2 and V3. This rhythm lasted more than 30 seconds with consecutive ventricular beats at a heart rate of more than 100 bpm. At the end of the tracing, note a fusion complex followed by sinus beats

right axis)], and bundle branch reentry VT should be considered.

Nonsustained VT

Nonsustained VT (NSVT) (Figs 136.8A and B) is a marker for increased risk of sudden cardiac arrest (SCA) in patients with prior MI and reduced left ventricular ejection fraction (LVEF).[10,11] Implantable cardioverter defibrillator (ICD) is indicated in patients with NSVT, LVEF < 40%, and inducible VT on EPS (mortality reduces from 50 to 24% over 5 years).[12,13]

However, patients with preserved LVEF (>55%) do not represent increased risk of SCA. Correcting electrolyte abnormalities and ruling out cardiac ischemia is sufficient. Beta blocker therapy is reasonable in symptomatic NSVT. There is no need to use antiarrhythmics, which may conversely increase mortality.[3,14]

Ventricular Fibrillation and SCA

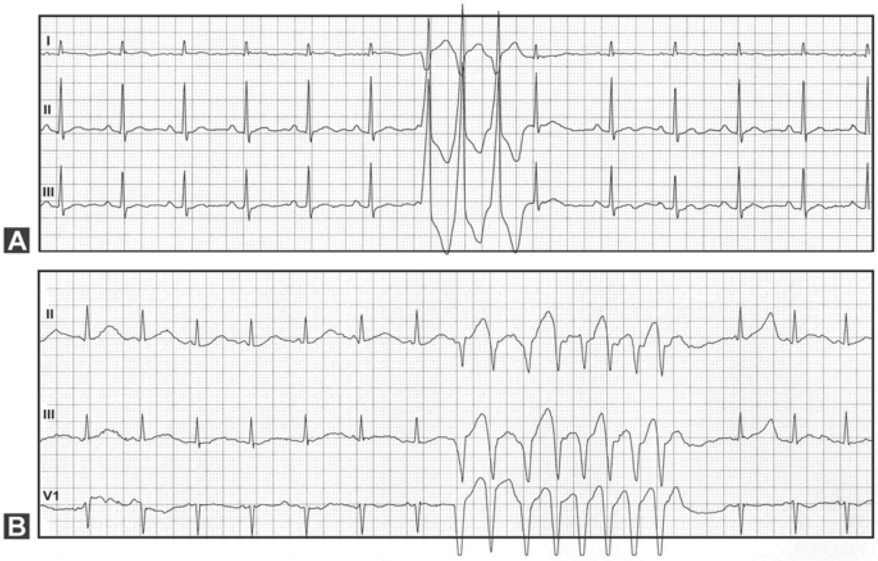
Ventricular fibrillation is a rapid, disorganized ventricular depolarization accompanied by loss of pumping action of the heart (Figs 136.9A to C). VT, both monomorphic and polymorphic, can degenerate into VF.

Acute management of sudden cardiac arrest is outlined in the advanced cardiac life support guidelines (Fig. 136.10). Postresuscitation deaths are highest in the first 24 hours; therefore, postresuscitation care, with IV antiarrhythmics and work-up for possible etiologies, is critical.[15,16] Reperfusion injury is associated with damaging biochemical reactions, which are suppressed by mild therapeutic hypothermia (MTH). Thus, the International Liaison of Committee on Resuscitation (ILCOR) recommends all unconscious VF adult patients with return of circulation after SCA should be cooled to 32 to 34° C for 12 to 24 hours.[16,17]

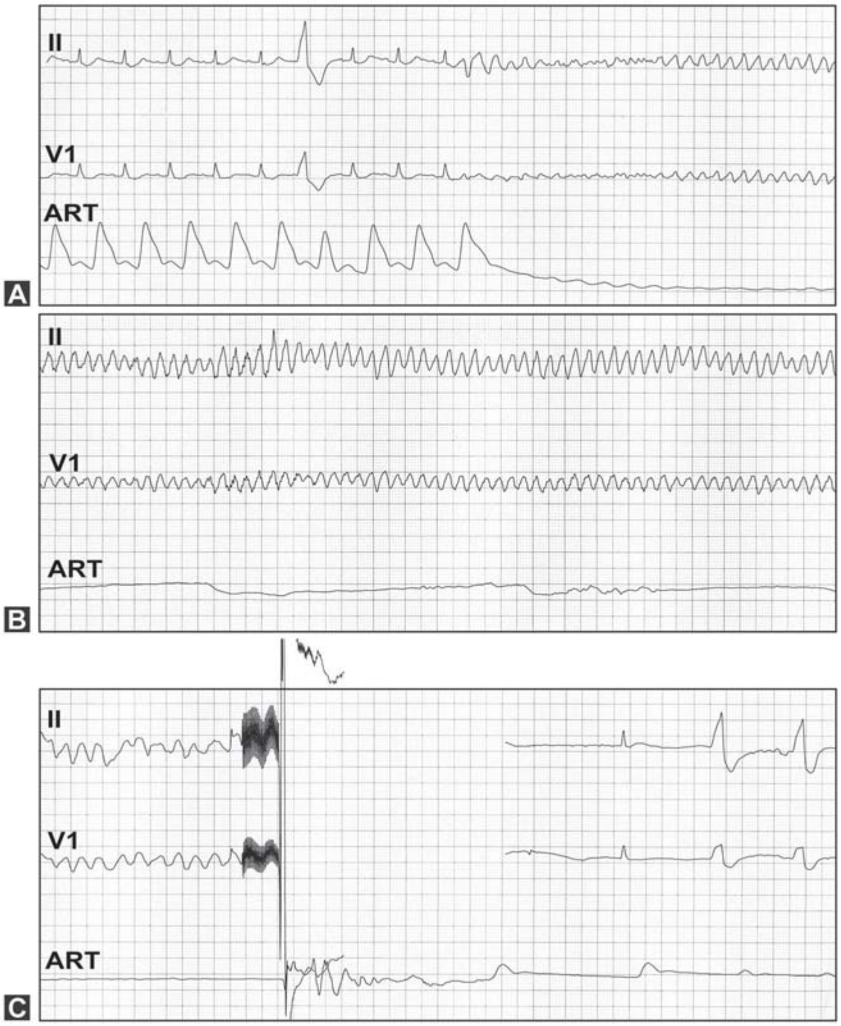
SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (>100 beats per minute) typically conducts to all Purkinje fibers at the same time, inscribing a narrow QRS. However, it can present with a WCT as described earlier.

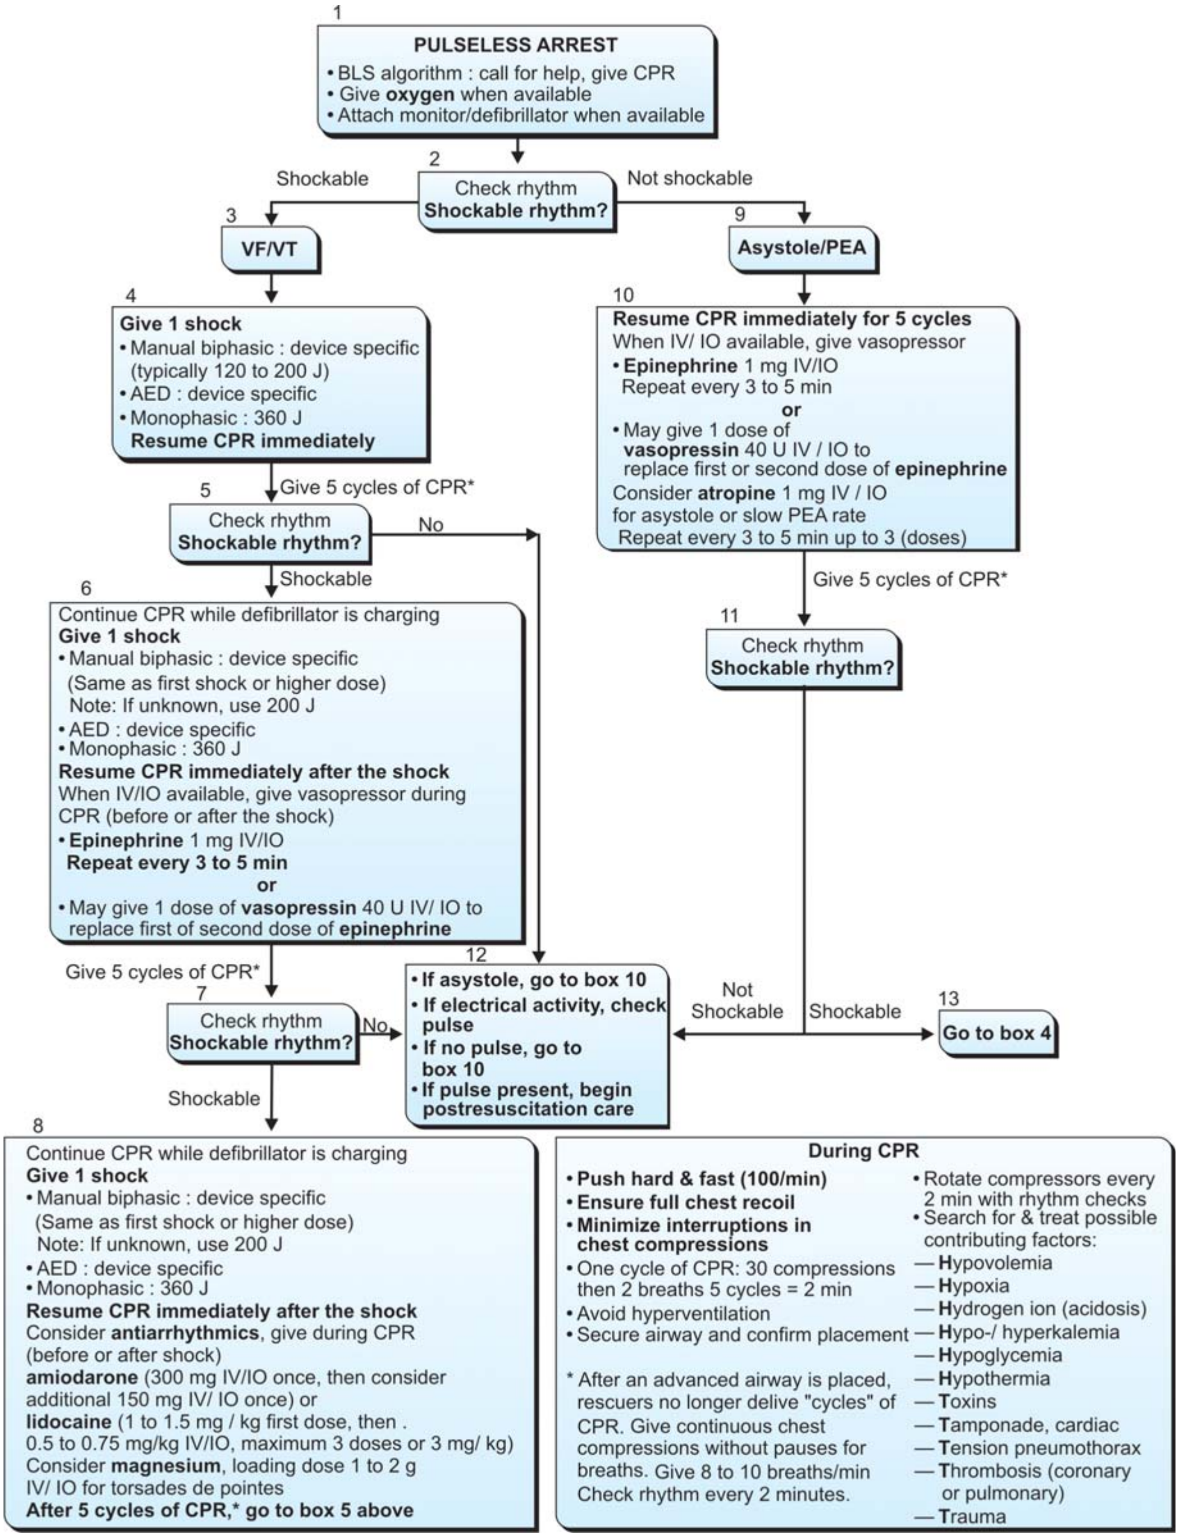
Supraventricular tachycardias are the most frequently encountered cardiac rhythm disturbances.[18,19] While SVT



Figs 136.8A and B: Nonsustained ventricular tachycardia (NSVT). Panel A: An electrocardiogram ECG of NSVT. It is defined as three or more consecutive ventricular beats with spontaneous termination in less than 30 seconds at a heart rate of more than 100 bpm. Note in Panel B the initial few beats demonstrate slight irregularity, but quickly settle into a regular rhythm



Figs 136.9A to C: Ventricular fibrillation (VF). Panel A: Electrocardiogram of VF. Note the abrupt onset of irregularly irregular wide complex tachycardia with fibrillatory waves. Panel B: The arterial line pulse wave tracing shows the fall in blood pressure and absence of pulse wave. Panel C: Also shown is the defibrillation, followed by resumption of QRS complexes and return of arterial pulse waveform



1
PULSELESS ARREST
• BLS algorithm : call for help, give CPR
• Give oxygen when available
• Attach monitor/defibrillator when available
2
Check rhythm
Shockable rhythm?
Shockable
Not shockable
3
VF/VT
9
Asystole/PEA
4
Give 1 shock
• Manual biphasic : device specific (typically 120 to 200 J)
• AED : device specific
• Monophasic : 360 J
Resume CPR immediately
Give 5 cycles of CPR*
5
Check rhythm
Shockable rhythm?
No
Shockable
6
Continue CPR while defibrillator is charging
Give 1 shock
• Manual biphasic : device specific (Same as first shock or higher dose) Note: If unknown, use 200 J
• AED : device specific
• Monophasic : 360 J
Resume CPR immediately after the shock
When IV/IO available, give vasopressor during CPR (before or after the shock)
• Epinephrine 1 mg IV/IO Repeat every 3 to 5 min
or
• May give 1 dose of vasopressin 40 U IV/ IO to replace first of second dose of epinephrine
Give 5 cycles of CPR*
7
Check rhythm
Shockable rhythm?
No
Shockable
8
Continue CPR while defibrillator is charging
Give 1 shock
• Manual biphasic : device specific (Same as first shock or higher dose) Note: If unknown, use 200 J
• AED : device specific
• Monophasic : 360 J
Resume CPR immediately after the shock
Consider antiarrhythmics, give during CPR (before or after shock)
amiodarone (300 mg IV/IO once, then consider additional 150 mg IV/ IO once) or
lidocaine (1 to 1.5 mg / kg first dose, then . 0.5 to 0.75 mg/kg IV/IO, maximum 3 doses or 3 mg/ kg)
Consider magnesium, loading dose 1 to 2 g IV/ IO for torsades de pointes
After 5 cycles of CPR,* go to box 5 above
10
Resume CPR immediately for 5 cycles
When IV/ IO available, give vasopressor
• Epinephrine 1 mg IV/IO Repeat every 3 to 5 min
or
• May give 1 dose of vasopressin 40 U IV / IO to replace first or second dose of epinephrine
Consider atropine 1 mg IV / IO for asystole or slow PEA rate Repeat every 3 to 5 min up to 3 (doses)
Give 5 cycles of CPR*
11
Check rhythm
Shockable rhythm?
Not Shockable
Shockable
12
• If asystole, go to box 10
• If electrical activity, check pulse
• If no pulse, go to box 10
• If pulse present, begin postresuscitation care
13
Go to box 4
During CPR
• Push hard & fast (100/min)
• Ensure full chest recoil
• Minimize interruptions in chest compressions
• One cycle of CPR: 30 compressions then 2 breaths 5 cycles = 2 min
• Avoid hyperventilation
• Secure airway and confirm placement
* After an advanced airway is placed, rescuers no longer delive "cycles" of CPR. Give continuous chest compressions without pauses for breaths. Give 8 to 10 breaths/min Check rhythm every 2 minutes.
• Rotate compressors every 2 min with rhythm checks
• Search for & treat possible contributing factors:
— Hypovolemia
— Hypoxia
— Hydrogen ion (acidosis)
— Hypo-/ hyperkalemia
— Hypoglycemia
— Hypothermia
— Toxins
— Tamponade, cardiac
— Tension pneumothorax
— Thrombosis (coronary or pulmonary)
— Trauma

Fig. 136.10: Advanced cardiac life support (ACLS) algorithm for approach and management of pulseless ventricular tachycardia or ventricular fibrillation. AED = Automated external defibrillator; BSL = Basic life support; CPR = Cardiopulmonary resuscitation; IV/IO = Intravenous/intraosseous infusion; PEA = Pulseless electrical activity; VF/VT = Ventricular fibrillation/ventricular tachycardia (From Part 7.2: Management of Cardiac Arrest. Circulation. 2005;112;IV-58-IV-66. Reproduced with permission from American Heart Association.)

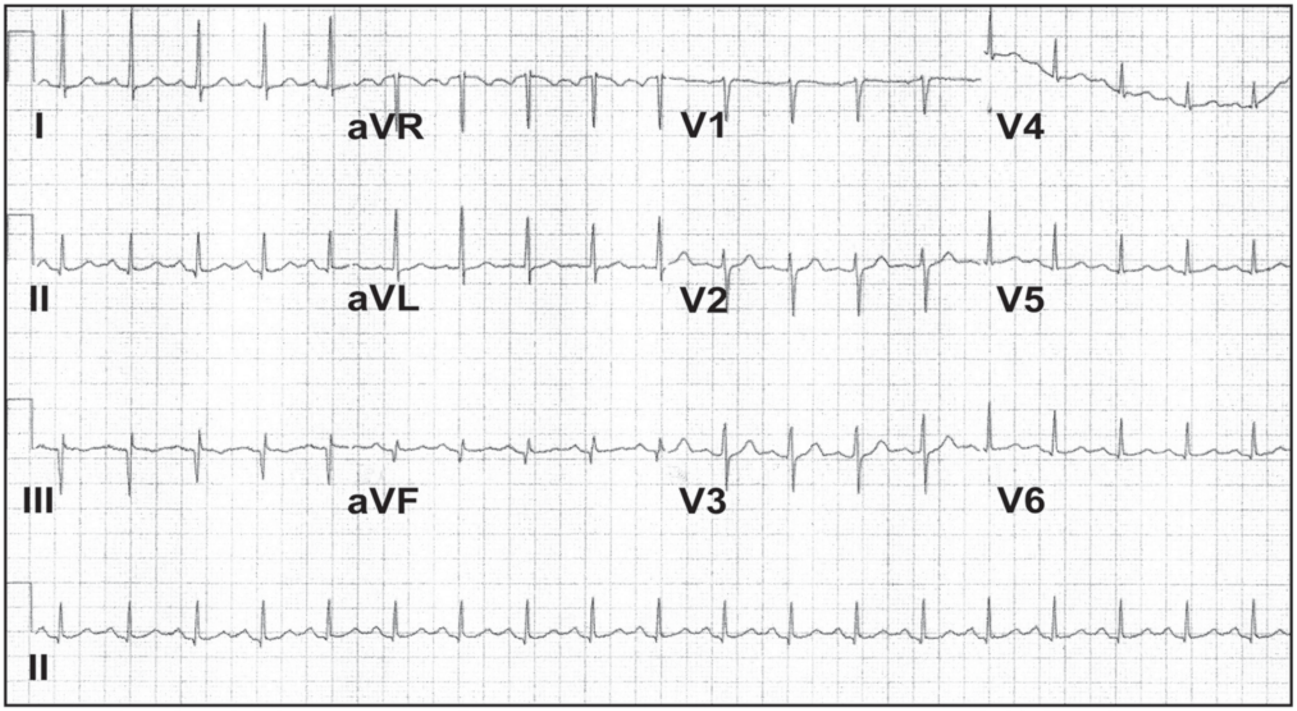


Fig. 136.11: Sinus tachycardia (ST). 12-lead electrocardiogram of ST with regular narrow QRS complexes and a 'P' wave preceding each QRS complex with rate greater than 100 bpm. The 'P' wave has the same morphology of the sinus 'P' (upright "+" in leads II, III and aVF, and converted "-" in lead aVR), and the 'PR' interval is constant

can be spontaneous, triggers include hypoxemia, hypovolemia, hyperthermia, hyperkalemia or hypokalemia, cardiac tamponade, tension pneumothorax, toxins, medications and drugs (caffeine, tobacco, alcohol, pseudoephedrine), pulmonary thromboembolism and, finally, the ubiquitous pain or stress. Supraventricular tachycardia includes the following:

Sinus Tachycardia

Sinus tachycardia (ST) is the most common SVT in the ICU. The rates are typically 100 to 160 bpm (lower than the usual paroxysmal supraventricular tachycardia rate) (Fig. 136.11). Sinus tachycardia is usually physiological (e.g. pain, fever, hypotension, hypoxia, drug-induced). Hence, management is alleviation of the cause. Rarely, ST needs to be slowed down by medication (e.g. beta blocker, calcium channel blocker or digoxin), such as in myocardial ischemia.

Atrial Fibrillation

After sinus tachycardia, the most common arrhythmia in the ICU is atrial fibrillation (AF) (Figs 136.12A and B), which is especially common after cardiac and thoracic surgery. It is usually associated with an irregular ventricular response, except in complete heart block, an accelerated junctional or idioventricular rhythm, or a ventricular-paced rhythm with AV block.

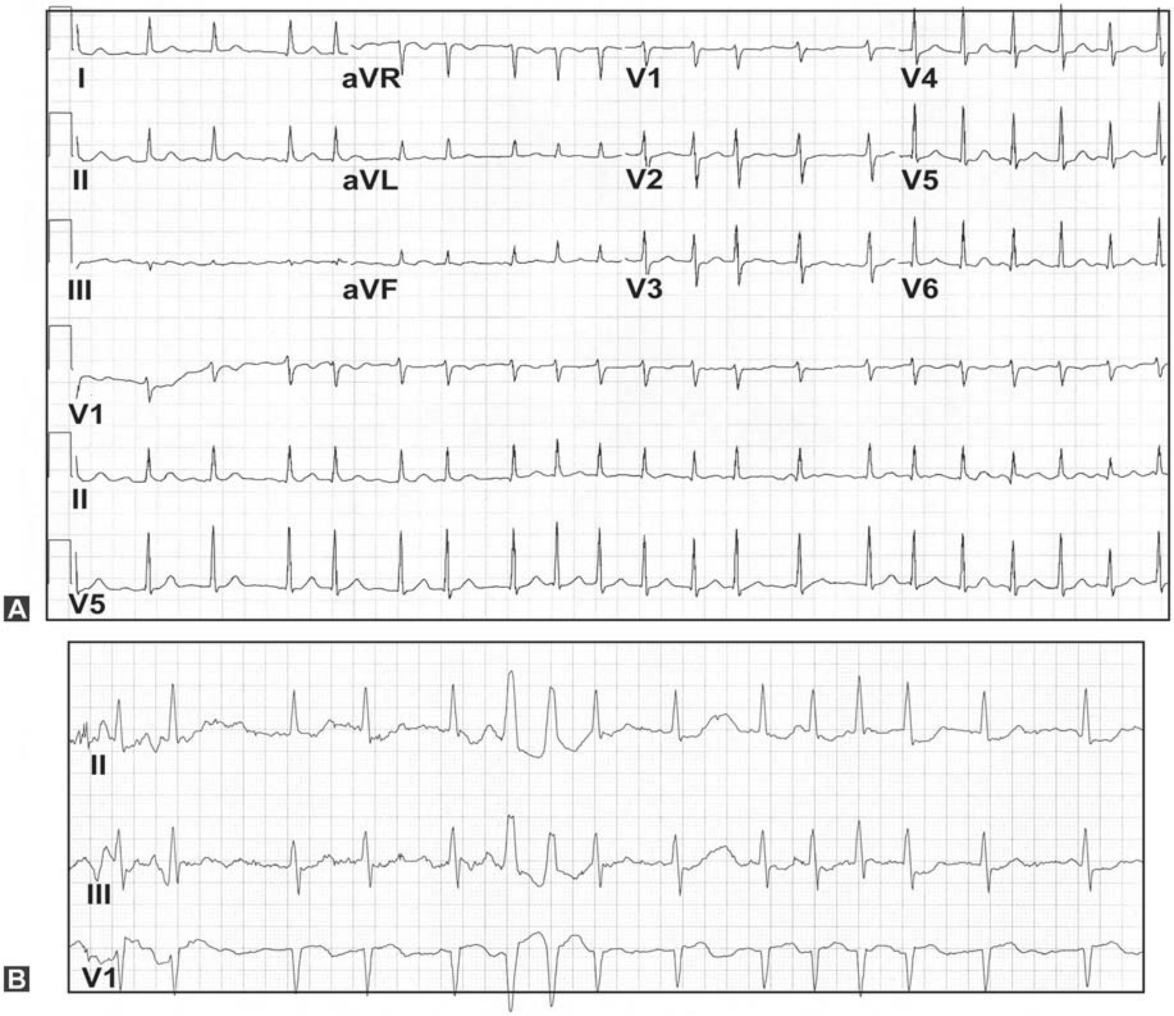
Symptoms in patients with atrial fibrillation range from minimal or no symptoms to palpitations, dizziness, syncope, chest discomfort or angina, worsening heart failure or even acute pulmonary edema. Management of atrial fibrillation in the ICU includes thromboembolic prevention and rhythm management.

Thromboembolic Prevention

Patients with AF have increased risk of thromboembolic events; therefore, anticoagulation is warranted, especially in the presence of:

1. Valvular disease (e.g. mitral stenosis or prosthetic heart valve).
2. Prior thromboembolism or persistent atrial thrombus.
3. Thyrotoxicosis.
4. High-risk patients with CHADS2 score $\geq$ 2 (cardiomyopathy = 1, hypertension = 1, age $\leq$ 75 years old = 1, age 65-74 = 0.5, diabetes mellitus = 1, stroke = 2, coronary artery disease = 0.5, female = 0.5).
5. Planned direct cardioversion and continue for at least 4 to 6 weeks post conversion.

Anticoagulation therapy with intravenous unfractionated or subcutaneous low-molecular weight heparin



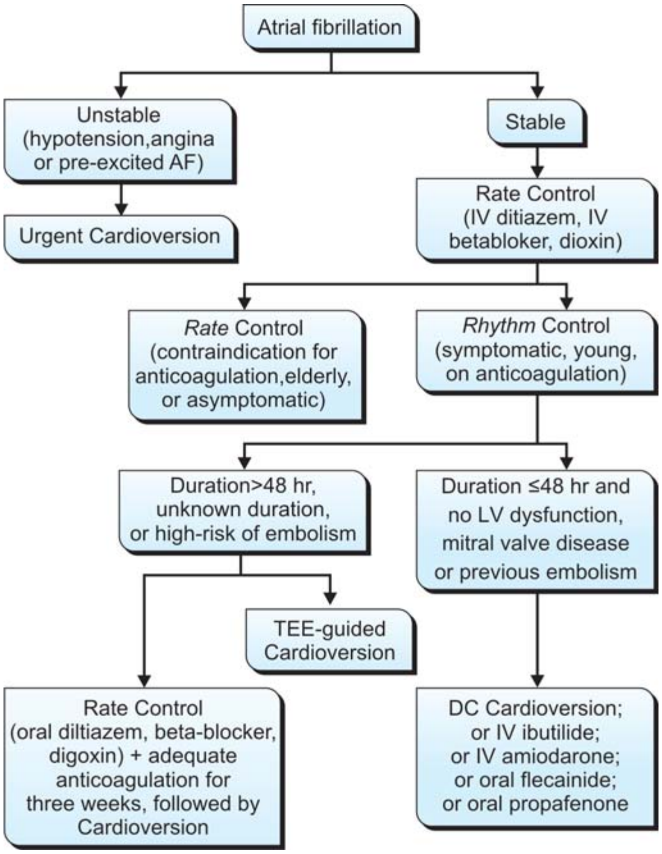
Figs 136.12A and B: Atrial fibrillation (AF). Panel A: Electrocardiogram (ECG) of AF with irregularly irregular narrow complex tachycardia with an undulating baseline with fibrillatory ‘P’ waves that vary in size, shape and timing called ‘f’ waves. Panel B: ECG of AF with short-long sequence preceding an aberrantly conducted beat (Ashman phenomenon)

therapy should be initiated along with warfarin until international normalized ratio (INR) is therapeutic. Target INR level is 2.0 to 3.0 (2.5-3.5 in valvular disease or presence of thrombus).

Antiplatelet therapy should be used in patients at low risk for thromboembolic events (CHADS score $\leq$1) or if anticoagulation is contraindicated (e.g. bleeding or post surgery).

Rhythm Management (Fig. 136.13)

Rate-control medication doses and comments are demonstrated in Table 136.3. Rhythm control algorithm and medication doses and comments are illustrated in Figure 136.14 and Table 136.4. It is important to recognize digoxin toxicity-induced arrhythmia (0.8-4% in the U.S.). Life-threatening arrhythmias due to delayed afterdepolarization or bradycardias due to excessive vagal tone usually occur at levels > 2.0 ng/mL. The classic arrhythmias include bidirectional ventricular tachycardia, AV junctional rhythms and atrial tachycardia (faster than AFL with isoelectric baseline between the ‘P’ waves) with AV block. Treatment consists of discontinuing digoxin, atropine for bradycardia and potassium replacement. Digoxin-specific Fab fragments (Digibind) is recommended in patients with life-threatening arrhythmias, unstable severe bradycardia, plasma potassium > 5 mEq/L, plasma



Atrial fibrillation
Unstable (hypotension,angina or pre-excited AF)
Stable
Urgent Cardioversion
Rate Control (IV ditiazem, IV betabloker, dioxin)
Rate Control (contraindication for anticoagulation,elderly, or asymptomatic)
Rhythm Control (symptomatic, young, on anticoagulation)
Duration>48 hr, unknown duration, or high-risk of embolism
Duration ≤48 hr and no LV dysfunction, mitral valve disease or previous embolism
TEE-guided Cardioversion
Rate Control (oral diltiazem, beta-blocker, digoxin) + adequate anticoagulation for three weeks, followed by Cardioversion
DC Cardioversion; or IV ibutilide; or IV amiodarone; or oral flecainide; or oral propafenone

Fig. 136.13: An approach to the rhythm management of atrial fibrillation in the ICU. AF = atrial fibrillation; IV = intravenous; LV = left ventricle; TEE = transesophageal echocardiogram

digoxin >10 ng/mL, ingestion of > 10 mg of digoxin in adults and > 4 mg in children and any digoxin toxic rhythm in the setting of an elevated digoxin level.[20]

Atrial Flutter

Atrial flutter (AFL) is characterized by organized 'P' waves with same morphology and axis at a rate of 250 to 350 bpm with intermittent AV conduction (2:1, 3:1 or 4:1 AV block). Typically, the ventricular rate is around 150 bpm with a 2:1 AV block (Fig. 136.15). Management of AFL is similar to AF in thromboembolic event prevention and rhythm management. Isthmus-dependent atrial flutter is easily treated by radiofrequency ablation, which is curative.

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia (MAT) (Fig. 136.16) typically is seen in patients with enlarged atria, chronic lung disease, congestive heart failure, electrolyte abnormalities and acid-base disturbance. Management includes alleviation of the cause and consideration of rate control with calcium channel blockers, beta blockers or digoxin. It is essential to differentiate it from AF since there is no need for anticoagulation therapy in MAT.

Other Types of SVTs

The other three types of SVTs [atrioventricular nodal reentry tachycardia (AVNRT), atrioventricular reentry tachycardia (AVRT) due to an AP (Wolff-Parkinson-White) and unifocal/ectopic atrial tachycardia (AT)] have almost similar electrocardiograms. All have narrow QRS tachycardia with 'P' wave either right after the QRS, "short RP tachycardia" (common AVNRT, orthodromic AVRT, or AT with first-degree AV block) (Fig. 136.17) or right before the QRS, "long RP tachycardia" (uncommon AVNRT, or AT). Typically there is sudden onset and sudden offset of the tachycardia with heart rate usually ranging between 160 and 200 bpm.

After obtaining a 12-lead ECG, blocking the AV node may help determine the type of SVT. Persistent 'P' waves in the absence of a QRS complex confirms the diagnosis of AT. However, blocking the AV node could terminate the SVT; then the only diagnostic tool would be an EP study. The AV node can be blocked by Valsalva maneuvers, carotid massage (only in young patients without carotid bruit) or AV blocking agents (e.g. adenosine, beta blockers, calcium channel blockers or digoxin).

Supraventricular tachycardia with hemodynamic instability needs immediate DC cardioversion (50J for SVT/AFL; 200J for AF). Hemodynamically, stable SVT can be treated by vagal maneuvers, or with one of the following medications:

- Intravenous adenosine (6 mg followed in 2 min with another 6 mg and in 2 more min with 12 mg).
- Diltiazem (0.25-0.35 mg/kg loading dose followed by infusion 5-15 mg/hour) – caution with hypotension.
- Beta blockers (metoprolol titrate 0.5-1 mg, esmolol 0.5 mg/kg/min for 1 min followed by 0.05-0.2 mg/kg/min) – caution with hypotension.
- Intravenous digoxin (1 mg over 24 hours in increments of 0.25-0.5 mg, followed by 0.125-0.25 mg daily).
- Intravenous amiodarone (loading dose of 150 mg over 10 min, may repeat if failed to control rate; followed by infusion 30 mg/hour) – especially in AF with presence of AP.

The best long-term management for AVNRT and AVRT is EPS and radiofrequency ablation.

TABLE 136.3: Commonly used medications for controlling ventricular rate in atrial fibrillation

Drug	*Control of Acute Episode*	*Control of Sustained Atrial Fibrillation*	*Comments*
Calcium channel blockers			
Diltiazem	20-mg bolus followed, if necessary, by 25 mg given 15 min later. Maintenance infusion of 5-15 mg/hr.	Oral controlled-release formulation, 180-300 mg daily.	Long-term control may be better with the addition of digoxin.
Verapamil	5-10 mg IV over 2-3 min, repeated once, 30 min later. Maintenance infusion rate is not reliably documented.	Slow-release formulation, 120-240 mg once or twice daily.	Causes elevation in digoxin level. May be more negatively inotropic than diltiazem.
Beta blockers†			
Esmolol	0.5 mg/kg of body weight IV, repeated if necessary. Follow with infusion at 0.05 mg/kg/min, increasing as needed to 0.2 mg/kg/min.	Not available in oral forms.	Hypotension may be troublesome but responds to drug discontinuation.
Metoprolol	5-mg bolus IV, repeated twice at intervals of 2 min. No data on maintenance infusion.	50-400 mg daily in divided doses.	Useful if there is concomitant coronary disease.
Propranolol	1-5 mg IV, given over 10 min.	30-360 mg in divided doses or in long-acting form.	Noncardioselective: use cautiously in patients with a history of bronchospasm.
Digoxin	1.0-1.5 mg IV or orally over 24 hr in doses of 0.25-0.5 mg.	0.125-0.5 mg daily.	Renally excreted. Slow onset even if given IV with less effective control than other agents, although may be synergistic with them. Poor efficacy for exertional heart rate control.

†The beta blockers listed are representative of agents in this category. Other intravenous or oral beta blockers may be equally acceptable. (From Falk RH. Atrial fibrillation. N Engl J Med 2001;344:1067-78. Copyright © Massachusetts Medical Society. All rights reserved.)

TABLE 136.4:.Medications used for conversion of atrial fibrillation and maintenance of sinus rhythm

Drug Name	*Conversion Dose*	*Oral Maintenance Dose*	*Comments*
Ibutilide	1 mg IV over 10 min if weight >60 kg. (For weight <60 kg, 0.01 mg/kg over 10 min. May repeat after 10 min of initial infusion.)	Not for maintenance.	Contraindicated in patients with hypokalemia, QT prolongation or history of torsades de pointes. Always use magnesium IV 2 gm before ibutilide.
Dofetilide	0.5 mg twice daily (adjust for renal disease).	0.5 mg twice daily.	Hospitalize for initiation.
Flecainide	300 mg oral. 2 mg/kg IV.	50-150 mg twice daily.	Only for paroxysmal AF with structurally normal heart
Propafenone	600 mg oral. 2 mg/kg IV.	150-300 mg twice daily.	Only for paroxysmal AF with structurally normal heart.
Amiodarone	1200 mg IV in 24 hr.	600 mg daily for 2 weeks, then 200-400 mg daily.	IV amiodarone moderately effective for cardioversion.
Dronedarone	400 mg twice daily oral.	400 mg twice daily.	Less effective than amiodarone for conversion. Lower risk of amiodarone-related side effects.
Sotalol	Low success rate. Not recommended for cardioversion.	120-160 mg twice daily.	Used primarily for maintenance of sinus rhythm. Hospitalize for initiation and monitor QT for prolongation.
Disopyramide	200 mg oral every 4 hr to max of 800 mg.	100-150 mg 4 times daily (200-300 mg controlled release formulation twice daily).	Negative inotropic effect. Can be used in hypertrophic cardiomyopathy.
Quinidine Sulfate	200 mg oral followed 2 hr later by 400 mg.	200-400 mg 4 times daily (gluconate 324-648 mg 3 times daily).	Long-term therapy associated with increased risk of death.

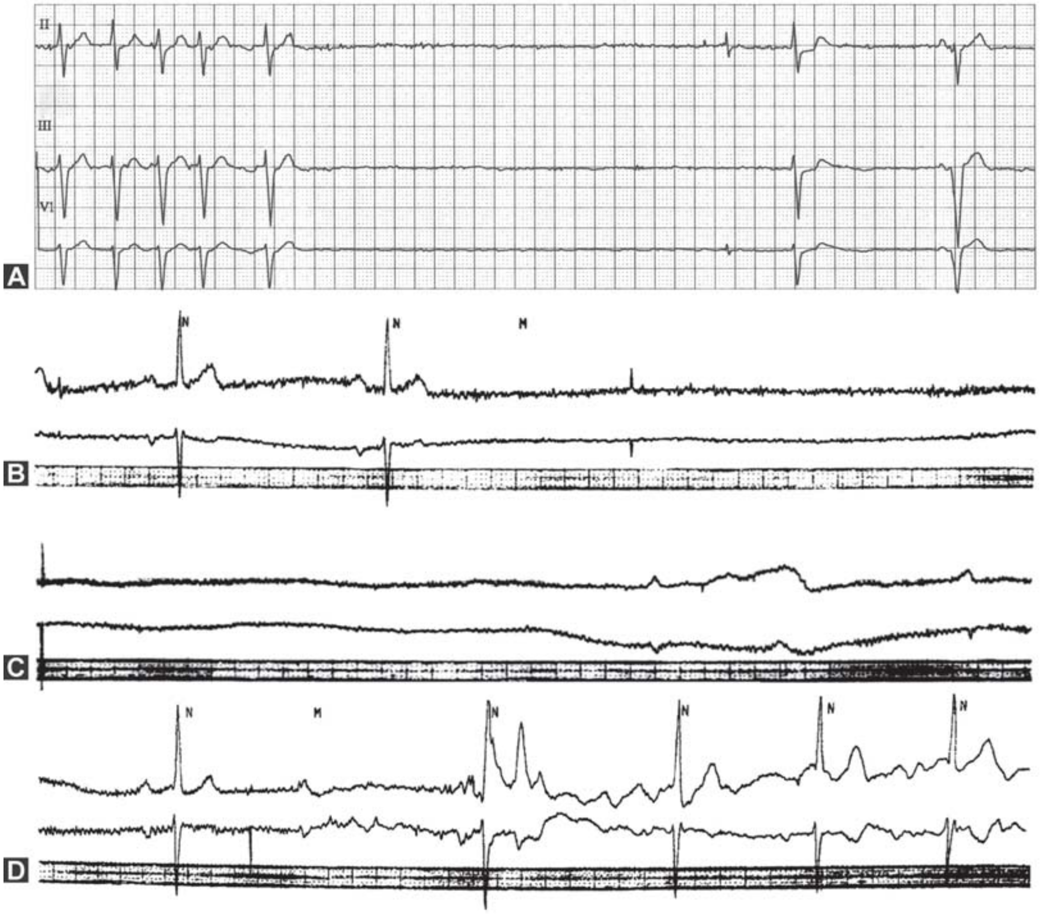
BRADYCARDIA (HEART RATE <60 BPM)

Bradycardia is due to:

1. Sinus node dysfunction (sinus bradycardia or sinus pause);
2. AV node dysfunction (first-, second- and third-degree AV block). Most bradycardias in ICU patients are induced by vagally mediated causes such as intubation, suctioning, increased intracranial pressure, urination, defecation, vomiting, or retching. Other extrinsic causes might include:
   - Drugs (beta blockers, calcium channel blockers, digoxin, antiarrhythmics)
   - Acute MI (inferior acute MI-related AV blocks, often transient; anterior acute MI-related AV blocks, often irreversible)
   - Electrolytes imbalance (K, Mg, Ca)
   - Hypothyroidism
   - Hypothermia
   - Sepsis
   - Specific infection (e.g., endocarditis, rheumatic fever, Lyme, Chagas)
   - Valvular disease (especially post valvular surgery)
   - Collagen disorder
   - Hypoxia (sleep apnea)
   - Advanced age (calcification)

Management includes eliminating the cause and possible pacing. Because transcutaneous pacing may be uncomfortable, it is intended to be temporary. Refer to cardiologist for transvenous pacing (TVP) in patients who require ongoing pacing. It is necessary to monitor the TVP once a day to ensure appropriate pacing



Figs 136.18A to D: Sinus pause. Panel A: Sinus pause is seen with sudden and prolonged cessation of atrial activity. No 'P' waves and no QRS complexes are seen. Junctional rhythm or ventricular escape rhythm usually takes over until the sinus recovers or pacemaker-induced atrial activity takes over the role of dominant pacemaker of the heart. Note that the preceding rhythm is atrial fibrillation with a long pause of 5 seconds followed by resumption of sinus beats. This is called "postconversion" pause. If longer than 5 seconds, it is an indication for permanent pacemaker. Panels B, C and D: Note the prolonged sinus pause, which occurred spontaneously in a patient with underlying sinus rhythm and spontaneous recovery. Some atrial activity ('P' waves) is noted in Panel C with no conduction to the ventricles. This occurred spontaneously in an ICU patient

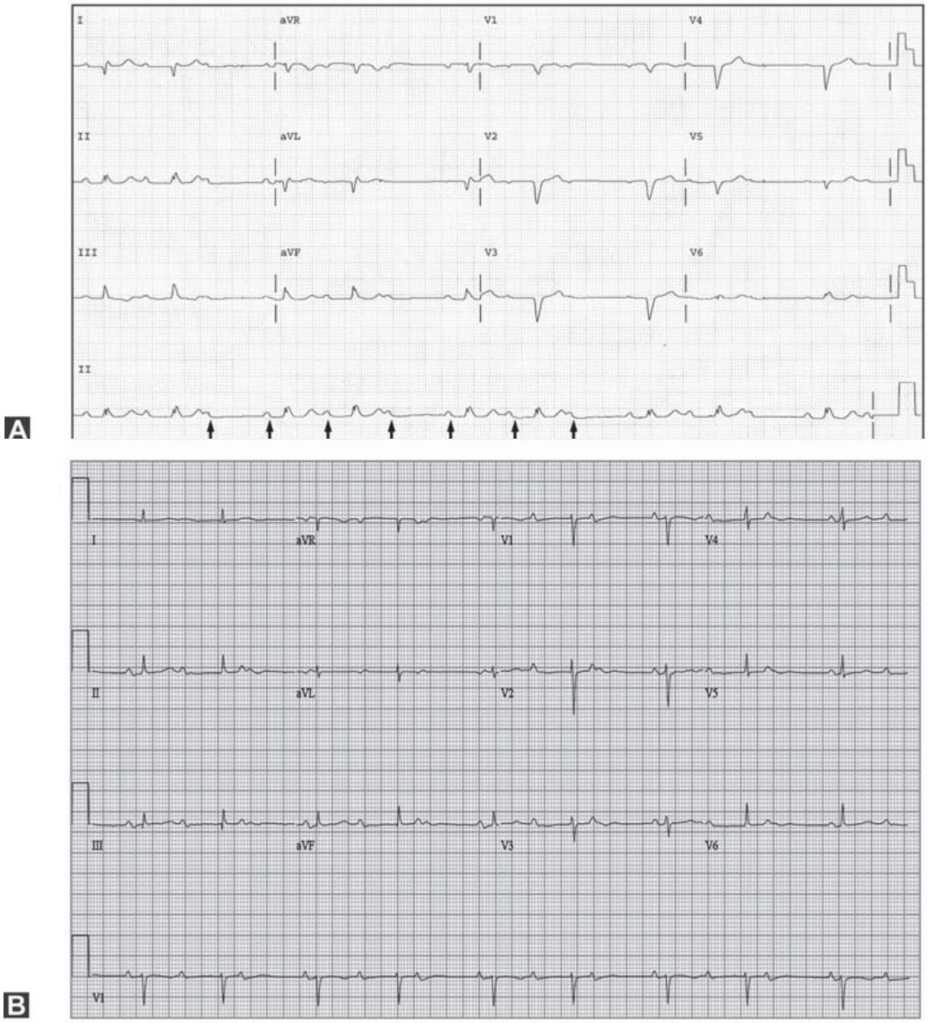
thresholds and sensing functions. Postcardiac surgery patients may have bradycardia due to local edema in the region of the AV node. Temporary pacing for 5 to 7 days is the first course of action; if no recovery, then permanent pacemaker implantation.

Sinus Node Dysfunction

If sinus node dysfunction (Figs 136.18A to D) persists after removing the cause and the patient is symptomatic, then medical management is warranted, which includes: immediate IV atropine (0.6 mg, max 3 mg), IV dopamine (2-5 mcg/kg/min), IV isopreterenol (0.5-10 mcg/min) (caution in ischemic heart disease), or IV glucagon (3-10 mg bolus followed by 2-5 mg/h infusion, in beta blocker overdose-induced bradycardia). Pacemaker (temporary or permanent) is indicated if symptomatic bradycardia and sinus pauses (>3 second while awake, >6 seconds while sleeping) are unrespon-sive to management.

First-degree AV Block

Defined as normal 'P' wave with increased 'PR' interval (>200 ms), first-degree block is usually in the AV node and needs no treatment. Pacemaker is indicated only if the patient is symptomatic with PR > 300 ms.



Figs 136.19A to B: Second-degree heart block Mobitz I (Wenckebach) and Mobitz II. Panel A: Second-degree Mobitz Type I AV block (Wenckebach) is characterized by a normal 'P' wave with constant 'P-to-P' interval; prolonging PR interval until one QRS fails to conduct, then PR interval shortens again. Panel B: ECG of second-degree Mobitz type II AV block, defined as normal 'P' wave with constant 'P-to-P' and PR intervals with sudden drop of one or two QRS complexes

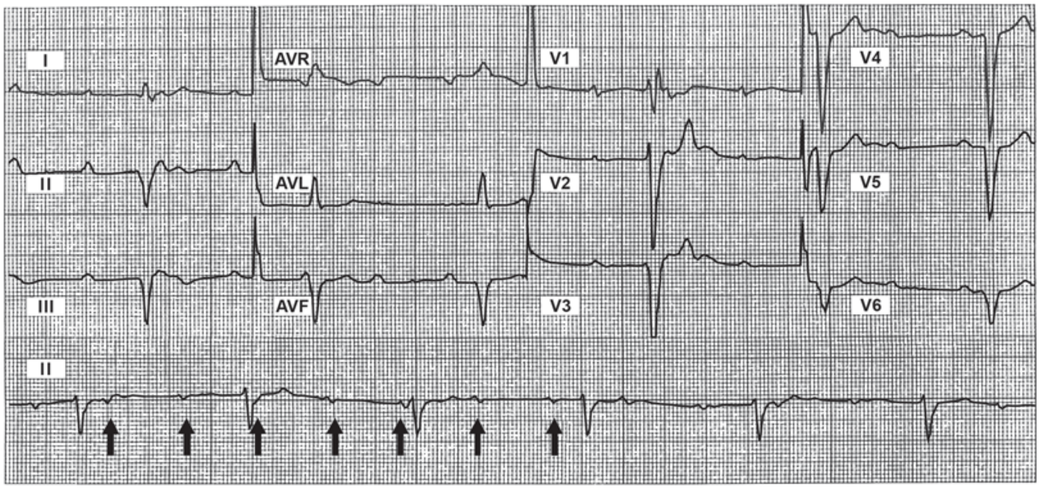


Fig. 136.20: Complete heart block or third-degree heart block. 12-lead electrocardiogram showing third-degree AV block with normal 'P' waves, constant PP intervals, constant PR intervals, and AV dissociation where the QRS complexes are less than 'P' waves

Second-degree AV Block, Type I (Mobitz I, "Wenckebach")

Location of second-degree, Type I block (Fig. 136.19A) is mostly in the AV node and needs no treatment other than removing any possible cause. Pacemaker is indicated only if the patient is symptomatic and failed other medical actions, especially if it is accompanied by fascicular block.

Second-degree AV Block, Type II (Mobitz II)

Second-degree, Type II block (Fig. 136.19B) can be unpredictable and lead to abrupt AV block with ventricular asystole due to the location of block (either intra- or infra-Hisian). If it persists after removing any possible cause, pacemaker should be considered.

Third-degree AV Block

Location of third-degree block (Fig. 136.20) is almost always below the His bundle. Thus, pacemaker is indicated in these patients. If a reversible cause is present (e.g. MI, Lyme disease, electrolyte imbalance, etc.), a temporary pacemaker should be placed until the condition resolves.

Cardiac Emergencies in the Intensive Care Unit: Cardiogenic Shock and Acute Coronary Syndrome

M Fuad Jan, Suhail Allaqaband

INTRODUCTION

Cardiogenic Shock (CS) is characterized by hypoperfusion of the extremities and vital organs and is defined by the following hemodynamic hallmarks:

1. Persistent hypotension (systolic blood pressure [SBP] < 80 to 90 mm Hg or mean arterial pressure 30 mmHg lower than baseline);
2. Severely reduced cardiac index (<1.8 L/min/m^2 without support or <2.0–2.2 L/min/m^2 with support)
3. Adequate or elevated ventricular filling pressure (e.g. Left Ventricular [LV] end-diastolic pressure >18 mmHg or Right Ventricular [RV] end-diastolic pressure >10-15 mmHg), a diagnosis usually made with the help of Pulmonary Artery (PA) catheterization.

ETIOPATHOGENESIS

Cardiogenic shock classically occurs in the setting of Acute Myocardial Infarction (AMI) associated with left ventricular dysfunction. Approximately 5 to 8% of patients hospitalized with ST-Elevation Myocardial Infarction (STEMI) and 2.5% of patients with non-STEMI (NSTEMI) have cardiogenic shock. Mortality due to CS is approximately 50% in the modern era.[1] The pathophysiology of CS involves a vicious cycle characterized by progressive myocardial dysfunction (Fig. 137.1). However, severe impairment of contractility is not necessary for CS, and conversely, LV Ejection Fraction (LVEF) may be only moderately depressed in CS,[1] while approximately half of all CS patients have small or normal LV size,[2,3] representing a failure of the adaptive mechanism of acute dilation to maintain stroke volume in the early phase of MI. Whereas LV failure or dysfunction resulting from acute ischemia is the predominant underlying theme in CS, RV dysfunction may also cause or contribute to CS. Shock due to isolated RV dysfunction carries nearly as high a mortality as LV shock. Predominant RV shock characterized by disproportionate elevation of right-heart filling pressures (RV end-diastolic pressure often >20 mmHg) and low-output hypotension despite preserved LV systolic function occurs in 5% of cases of CS complicating MI.[4]

Since MI with LV failure is the most common cause of CS, it is critical to exclude complicating factors that may cause shock in MI patients. Among these are the mechanical complications of ventricular septal rupture, contained free wall rupture and papillary muscle rupture. Mechanical complications must always be strongly suspected in patients with CS complicating nonanterior MI, particularly a first MI, and echocardiography remains the benchmark of cardiac imaging for the diagnosis of these usually fatal complications. Hemorrhage, infection and/or bowel ischemia may contribute to shock in the setting of MI and a high index of suspicion is required to make these diagnoses in MI patients, since survival may depend on their timely recognition and treatment.[1]

During the initial management strategy, it is also important to consider other causes of acute LV or RV dysfunction that may lead to CS. Acute myopericarditis, takotsubo (stress-induced) cardiomyopathy and hypertrophic cardiomyopathy can all present with ST elevation, elevated cardiac biomarkers and shock in the absence of significant coronary artery disease. Fig. 137.1: The classic pathophysiology of cardiogenic shock with progressive left ventricular dysfunction. Essentially, myocardial ischemia and infarction results in both systolic and diastolic dysfunction along with activation of the neurohormonal cascade. Left ventricular pump failure is a self-propagating cycle with continually worsening hemodynamics and eventually LV failure and death. NSTEMI = Non-ST-Elevation Myocardial Infarction; STEMI = ST-Elevation Myocardial Infarction; PCWP = Pulmonary Capillary Wedge Pressure; IL-6 = Interleukin-6; TNF-α = Tumor Necrosis Factor-Alpha

induced cardiomyopathy, a syndrome of acute LV failure after emotional or respiratory distress, can be complicated by CS in up to 4.2% of cases,[5] while acute valvular regurgitation, secondary to infective endocarditis or chordal rupture due to trauma or degenerative disease, may also cause CS. Aortic dissection may also lead to CS via severe aortic insufficiency or MI. Acute stress in the setting of aortic or mitral stenosis can also cause shock. Cardiac tamponade or massive pulmonary embolism can present as cardiogenic shock without associated pulmonary congestion.

Although the vast majority of patients with CS have a high Systemic Vascular Resistance (SVR) triggered by the compensatory release of catecholamines, vasopressin and angiotensin II in response to hypoperfusion, this reflex mechanism is not always fully effective as demonstrated by variable SVR, with median SVR during CS in the normal range despite vasopressor therapy. This is documented in the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial results.[6] In some patients, SVR may be low, similar to septic shock. In fact, sepsis was suspected in 18% of the SHOCK trial cohort, 74% of whom developed positive bacterial cultures.[6] SVR was lower in these patients and low SVR preceded the clinical diagnosis of infection and culture positivity by days. This is consistent with the observation that MI can cause Systemic Inflammatory Response Syndrome (SIRS) and the inappropriate vasodilatation that is a part of SIRS can result in impaired perfusion of the intestinal tract, enabling transmigration of bacteria and sepsis.

It is also important to note that approximately three-fourths of patients with CS complicating MI develop shock after hospital presentation,[7,8] and several classes of medications used to treat MI have been associated with

Fig. 137.2: Cardiogenic shock occurs in a significant number of patients after admission to hospital, and pharmacologic intervention is a contributory factor in many. Several classes of medication are associated, as shown, and although each is associated with only a small excess risk, the large number of patients treated with these medications can translate into a substantial number of events. Deleterious effect of volume expansion when used in excess for RV configuration is shown. LVEDP = Left Ventricular End Diastolic Pressure; PCWP = Pulmonary Capillary Wedge Pressure, CO = Cardiac Output; SIRS = Systemic Inflammatory Response Syndrome, RVEDP = Right Ventricular End Diastolic Pressure, RVEDV = Right Ventricular End Diastolic Volume. *Reverse Bernheim effect describes a condition where volume or pressure overload of RV causes a shift of the interventricular septum, which causes impairment of LV filling and contraction

shock, including beta-blockers, angiotensin-converting enzyme inhibitors, diuretics and morphine. As depicted in Figure 137.2, MI may lead to pulmonary edema even without a decrease in cardiac output (the earliest effect of ischemia is often a decrease in LV compliance or acute diastolic dysfunction) and redistribution of intravascular volume into the lungs may lead to an acute decrease in circulating plasma volume in those without prior heart failure. Thus, when high-dose diuretics are administered, plasma volume declines further.[1]

CLINICAL PRESENTATION AND DIAGNOSIS

Cardiogenic shock in AMI usually occurs in the context of risk factors, such as old age, anterior MI, hypertension, diabetes mellitus, multivessel coronary artery disease, prior MI or angina, prior diagnosis of heart failure, STEMI and left bundle branch block.[9] Clinical presentation is usually dramatic, with hypoperfusion manifesting clinically as cool extremities, decreased urine output and/or alteration in mental status. More often, however, CS evolves over several hours, or may develop during hospitalization as mentioned earlier. In the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) trial, CS developed during hospital admission in 89% of cases with cardiogenic shock,[10] while median delay from onset of AMI to CS in the SHOCK trial and the SHOCK trial registry was 5.6 and 7 hours, respectively.[6,7]

Chest Roentgenogram (CXR), Electrocardiogram (ECG) and cardiac biomarkers are usually the initial investigations undertaken. The CXR can provide valuable clues about the presence of infection, pulmonary edema or aortic dissection, while a normal ECG makes CS due to myocardial infarction highly unlikely. Hemodynamic criteria (see CS definition) suggestive of cardiogenic shock include the presence of sustained hypotension with a decreased urine output (<0.5 ml/kg/min), increased pulmonary capillary wedge pressure, increased right atrial pressure (>20 mm Hg), decreased cardiac output and increased systemic vascular resistance (>2100 dynes/cm^2).

Many of the hemodynamic criteria of CS are obtained by Right Heart Catheterization (RHC). Although routine use of RHC has been associated with increased mortality in a well-known and quoted study,[11] data from GUSTO-I[12] and the SHOCK registry[13] suggest that it is not harmful, and possibly beneficial, in terms of outcome. The mortality rate was lower in patients who underwent RHC than in those who did not (45.2 vs. 63.4%) in the GUSTO-I population. In the SHOCK registry, no increase was reported in the in-hospital mortality among patients undergoing right heart catheterization. The current American and European guidelines recommend RHC for patients who have STEMI, or who have progressive heart failure, cardiogenic shock, or mechanical complications, despite the paucity of evidence proving its efficacy.[14,15] It should be stressed, however, that there are no data regarding the optimal hemodynamic values to be targeted in cardiogenic shock patients.

Doppler echocardiography continues to be an excellent modality for hemodynamic assessment and evaluation of myocardial and valvular function and also mechanical complications related to CS. It is a routine assessment tool in patients with suspected myocardial infarction and cardiogenic shock, and can be readily performed by the patient's bedside. For example, in the SHOCK trial,[3] 175 echocardiograms were performed within 24 hours of randomization (64%), while in the Euro-Heart-Survey, 68% of cardiogenic shock patients underwent an echocardiographic evaluation.[16] Due to the ease and speed of availability, it is not surprising that this noninvasive method has supplanted RHC use in many patients with suspected cardiogenic shock.

TREATMENT

Treatment usually involves general supportive measures and pharmacological and mechanical interventions. Aspirin and intravenous Unfractionated Heparin (UFH) is routinely administered as recommended for MI. Clopidogrel is sometimes deferred until after emergency coronary angiography, because on the basis of angiographic findings, coronary artery bypass grafting (CABG) may need to be performed immediately. However, all patients who undergo percutaneous coronary intervention (PCI) receive a loading dose of 300 to 600 mg clopidogrel. Negative inotropes and vasodilators (including nitroglycerin) are avoided, while arterial oxygenation and near-normal pH are maintained in order to minimize ischemia. A low threshold for mechanical ventilation via mask or endotracheal tube is maintained.

Although, there has been a decline in PA catheter (Swan-Ganz) use due to controversy sparked by a prospective observational study suggesting that PA catheters were associated with poor outcomes,[11] Swan-Ganz catheterization continues to be important in establishing the relationship between filling pressures and cardiac output in the individual patient, and therefore supplementing clinical assessment of responses with this data.[1] Individualized PA catheter use is recommended for severely hypotensive MI patients.[14]

Pharmacotherapy

Pharmacotherapy in CS includes inotropic and vasopressor support. Inotropes are central in treatment because the initiating event in CS is contractile failure. Unfortunately, inotropes increase myocardial ATP consumption, and the short-term hemodynamic improvement afforded by them may occur at the cost of increased oxygen demand in a failing heart. On the other hand, higher doses of vasopressors are also associated with poor survival in CS, representing both more severe underlying hemodynamic derangement and direct toxic effects.[17] However, inotropic and vasopressor support is always required to maintain coronary and systemic perfusion until (and often after) an intra-aortic balloon pump (IABP) is placed or until shock resolves. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend norepinephrine for more severe hypotension because of its high potency,[14] and although both dopamine and norepinephrine have inotropic properties, dobutamine is also often needed.

Mechanical Support

IABP

Intra-aortic balloon counterpulsation remains the most widely used circulatory assist device in CS, and with advanced technology, including smaller diameter catheters, sheathless insertion techniques and enhanced automation, greater efficacy and safety has been achieved. Use of an IABP (Table 137.1) improves

TABLE 137.1: Effects of intra-aortic balloon pump in cardiogenic shock

Left Ventricular (LV) Myocardium	1.	↓ Volume
	2.	↓ wall tension
	3.	↓ systolic pressure
	4.	↓ LV end-diastolic pressure
Aorta	1.	↓ systolic pressure
	2.	↓ diastolic pressure
Coronary Blood Flow	1.	Increased*

*Balloon inflation causes "volume displacement" of blood within the aorta, both proximally and distally, leading to an increase in coronary blood flow and enhanced systemic blood flow by augmentation of the intrinsic "Windkessel effect," whereby potential energy stored in the aortic root during systole is converted to kinetic energy with the elastic recoil of the aortic root.

coronary and peripheral perfusion via diastolic balloon inflation that augments coronary perfusion and via systolic balloon deflation with an acute decrease in afterload that improves LV performance. It also increases collateral blood flow, improves subendocardial oxygenation and decreases myocardial oxygen consumption.

Intra-aortic balloon pump support should be instituted as quickly as possible – if a skilled operator is available and insertion can be performed quickly. In the large National Registry of Myocardial Infarction, IABP use was independently associated with survival at centers with higher rates of IABP use, whether PCI, fibrinolytic therapy or no reperfusion had been used[18]; although no completed trials to date demonstrate its benefit. Complications associated with IABP in the largest series so far demonstrate overall and major complication rates of 7.2 and 2.8%, respectively[19] and risk factors for complications identified include, female sex, small body size and peripheral vascular disease.

Left Ventricular Assist Device (LVAD) use has also been attempted in CS, but is limited by the need for a surgical procedure. However, recently, percutaneous LVADs have been introduced into practice and can be used to rapidly establish mechanical circulatory support in the catheterization laboratory. The Impella Recover® LP 2.5 system (ABIOMED Inc., Danvers, MA) is one such percutaneous LVAD implanted through a 13 French sheath in the common femoral artery and inserted through the aortic valve into the left ventricle, providing axial flow to the ascending aorta at a maximum flow rate of 2.5 L/min. In a prospective, randomized study of 26 patients[20] with CS (n = 13 IABP, n = 12 Impella LP 2.5), the Cardiac Index (CI), after 30 min of support, was significantly increased in patients with the Impella LP 2.5 compared with patients with IABP (Impella: change in CI = 0.49 ± 0.46 $l/min/m^2$, IABP: change in CI = 0.11 ± 0.31 $l/min/m^2$; $p = 0.02$). However, overall 30-day mortality was 46% in both groups. Thus, a percutaneously placed LVAD is feasible and safe to use and may provide superior hemodynamic support compared with standard treatment using an IABP. In our institution, we have also successfully used the Impella device and IABP simultaneously in patients with refractory and profound cardiogenic shock.[21]

Of the implantable Mechanical Circulatory Support (MCS) systems, the percutaneous ventricular assist device TandemHeart® pVAD™ system (Cardiac Assist, Inc., Pittsburgh, PA) has also been used to support patients in cardiogenic shock until cardiac recovery occurs or as a bridge to definitive therapy.[22] The device is a left atrial-to-femoral artery bypass system comprising a transseptal cannula, arterial cannulae and a centrifugal blood pump. The pump can deliver flow rates up to 4.0 L/min at a maximum speed of 7,500 revolutions per minute.

Revascularization

The survival benefit of early revascularization in CS was convincingly established in the randomized SHOCK trial, which found a 13% absolute increase in one-year survival in patients assigned to early revascularization (number needed to treat is <8 patients to save one life).[23,24] Numerous registry studies have also confirmed the survival benefit of early revascularization (surgical or PCI) in both the young and the elderly, including the incomplete randomized Swiss Multicenter Study of Angioplasty for Shock,[25] and it is observed that earlier the revascularization, the better the survival benefit seen, for as long as 48 hours after MI and 18 hours after shock onset. PCI with stenting and use of glycoprotein IIb/IIIa inhibitors is independently associated with improved outcomes in CS patients.[26,27] Among patients with CS undergoing PCI, age and time from symptom onset to PCI and post-PCI Thrombolysis In Myocardial Infarction (TIMI) flow grade are independent predictors of mortality.[24,26] Figure 137.3 relates the ACC/AHA guidelines for revascularization in patients with cardiogenic shock, with early revascularization recommended for patients <75 years (Class I) and for suitable candidates ≥ 75 years (Class IIa).

In contrast to PCI, thrombolytic therapy in CS is probably futile and this is supported by data from the SHOCK registry,[28] where patients receiving thrombolysis

had similar mortality compared to thrombolytic-eligible patients who did not receive thrombolysis (61 vs. 71%; p = 0.334).

In summary, rapid evaluation and early initiation of the definitive therapy for CS (revascularization) affords a reasonable chance for full recovery as demonstrated by the SHOCK trial,[24] where the three- and six-year survival rates in patients with CS were respectively 41.4 and 32.3%, i.e. persistent treatment benefit. An early invasive revascularization approach is associated with benefit at every level of risk, with potential for full recovery and improved quality of life.

ACUTE CORONARY SYNDROME

Definition and Classification

Acute Coronary Syndrome (ACS) is an operational term that refers to a constellation of clinical symptoms and signs that are compatible with acute myocardial ischemia. It is often due to rupture of atherosclerotic plaques that contain large necrotic cores and although substantially large, are often positively remodeled (Glagov effect) and may not always compromise luminal integrity. Such plaques (also called vulnerable plaques) are covered by a thin, intact fibrous cap (cap thickness < 65 micrometers), which is inflamed with macrophages. Although plaque rupture and intraluminal obstruction are the most common mechanisms underlying ACS, in the CASPAR study,[29] nearly 25% of patients with ACS undergoing coronary angiography did not have a culprit lesion, thereby suggesting that coronary artery endothelial dysfunction, in addition to vessel morphology, can play a critical role in ACS.

Clinically, plaque rupture results in thrombus formation with complete vessel occlusion (fibrin-rich clot) in acute STEMI, or a nonoccluding thrombus (platelet-rich clot) in unstable angina or non-STEMI (also referred to as non-ST-segment elevation acute coronary syndrome [NSTE ACS]).[30] The Joint Task Force of the European Society of Cardiology, American College of Cardiology Foundation, the American Heart Association and the World Health Federation defines acute MI as a clinical event consequent to the death of cardiac myocytes (myocardial necrosis) that is caused by ischemia. In the spectrum of ACS, NSTEACS is defined by electro-cardiographic ST-segment depression, prominent T-wave inversion, and/or positive biomarkers of necrosis (e.g. troponin) in the absence of ST-segment elevation in an appropriate clinical setting (chest discomfort or angina equivalent) (Fig. 137.4).

In 2007, the Joint Task Force also introduced a clinical classification of MI[31] according to the proximate cause of the myocardial ischemia with implications for differing treatment approaches (Table 137.2).

Challenges for implementing the new definition and classification include the interpretation of raised troponin levels in the context of other plausible differential diagnoses (Table 137.3). In this regard, the clinician must be aware of the pitfalls of interpreting elevated troponin levels solely as ACS without assessing the entire clinical context.

14. Transplant vasculopathy	14. Critically ill patients with respiratory failure*
15. Chemotherapy (adriamycin, 5-FU, daunorubicin, etc.)	
16. Systemic vasculitis	
17. Rheumatoid arthritis	
18. Rheumatic fever	
19. Left ventricular hypertrophy	
20. Sympathomimetic drugs/overdose	

Alternative causes of an elevated troponin in the absence of a thrombotic acute coronary syndrome. Many of these elevations arise from a combination of demand ischemia (supply-demand mismatch), ventricular wall stretch, decreased perfusion pressure, direct myocardial damage, or imbalance of the autonomic nervous system.

*Most frequent causes in the ICU.

MANAGEMENT OF ACS

Early recognition of ACS symptoms is critical for timely management (Fig. 137.5). An ECG and an abbreviated history and physical examination should be obtained rapidly in patients suspected to have ACS and patients should be stratified based on their risk early on in the course of their illness (Table 137.4). All patients in the ICU consulted for chest discomfort or other symptoms suggestive of ACS (Table 137.5) should be promptly evaluated and treated, usually on the basis of a predetermined, institutional ACS protocol, which should include several different possibilities (Fig. 137.6). An ECG should be obtained and interpreted immediately by the consulting or ICU resident. For cases in which the initial diagnosis and treatment plan are unclear to the initial evaluating physician, immediate cardiology consultation is advisable.

Acute Phase Pharmacotherapy

Contemporary management of ACS involves a complex array of antithrombotics, including dual oral antiplatelet

TABLE 137.4: Risk assessment tools in acute coronary syndrome

TABLE 137.5: Symptoms and signs of acute coronary syndrome

Symptoms	*Signs*
Clinical Features	
1. Circadian periodicity with peak incidence of events between 6 AM and noon	1. Clenched fist held against sternum (Levine sign)
2. Chest discomfort described as a heavy weight, squeezing, choking or heavy pain; can be associated with a general feeling of malaise or exhaustion	2. Bradycardia or sinus tachycardia
3. Nausea and vomiting due to the activation of vagal reflexes; occasionally, patients may complain of diarrhea or a violent urge to defecate	3. Fever up to 101–102ºF (rectal)
4. Other symptoms may include dizziness, palpitations, cold perspiration, and cough productive of pink frothy sputum (e.g. in pulmonary edema)	4. Tachypnea; Cheyne-Stokes respiration in elderly patients with cardiogenic shock or heart failure
	5. Elevated JVP in pulmonary edema and right ventricular infarction
	6. Rales in patients with left ventricular failure; in such patients diffuse wheezing may occur*
	7. Soft or muffled first heart sound (S1) to a universally present fourth heart sound (S4)[†]
	8. Systolic murmur[§]
	9. Pericardial friction rub[#]

Table listing some of the important features on history and physical examination in patients with ACS.

*In 1967, Killip proposed a prognostic classification on the basis of presence and severity of rales in patients with STEMI: Class I patients have no rales or third heart-sound (S3); Class II patients have rales at <50% of lung fields ± S3; Class III patients have rales in >50% of each lung field; Class IV patients are in cardiogenic shock.

[†] A third heart sound (S3) in patients with ACS usually reflects severe left ventricular dysfunction with elevated filling pressures.

[§] Transient or persistent systolic murmur is usually secondary to papillary muscle dysfunction.

[#] This is usually heard in patients with STEMI sustaining large transmural infarctions.

therapy (aspirin plus a thienopyridine) and an anticoagulant. The clinical challenge is the optimal combination of these therapies for effective suppression of ischemic events, while avoiding bleeding events.

Antiplatelet Therapies

Since early fibrinolytic studies,[32] aspirin (150 to 325 mg) has been the mainstay treatment for patients undergoing either pharmacological or catheter-based reperfusion. All patients with ACS and without contraindications benefit from 150 to 300 mg of aspirin.[33, 34]

The thienopyridine clopidogrel, which irreversibly blocks the Adenosine Diphosphate (ADP) receptor P2Y12 on platelets, has also become an essential component of therapy in patients with ACS because it helps significantly improve outcome. When comparing clopidogrel 300 mg loading and 75 mg daily dosage with placebo on a background of aspirin in NSTEACS patients, a 20% Relative Risk Reduction (RRR) in cardiovascular death, nonfatal MI and stroke was observed (clopidogrel 9.3% vs. placebo 11.4%; relative risk [RR] 0.80, 95 confidence interval [CI] 0.72-0.90, $p < 0.001$).[35] A higher loading dose of clopidogrel (600 mg) has also been shown to achieve more rapid platelet inhibition,[36] and in the recently presented CURRENT-OASIS-7 trial (European Society of Cardiology 2009 meeting, Barcelona, Spain) comparing two different regimens of clopidogrel (loading/maintenance dose regimens of 300/75 mg vs. 600/150 [1 week] to 75 mg) and aspirin (75–100 mg vs. 300–325 mg), there was a significant (15%) reduction in cardiovascular death, MI and stroke in the higher-dosed clopidogrel group.

Prasugrel — a newer thienopyridine that irreversibly binds to P2Y12 — has a more rapid onset of action and a stronger inhibitory effect than clopidogrel.[37] In comparison with clopidogrel, prasugrel shows lower variability in platelet response and no measurable vulnerability to genetic variation in CYP isoenzymes. In a randomized controlled trial[38] of moderate-to high-risk ACS patients, the primary efficacy endpoint occurred in 12.1% of patients receiving clopidogrel and 9.9% of patients receiving prasugrel (Hazard Ratio [HR] for prasugrel vs. clopidogrel, 0.81; 95% CI, 0.73-0.90; $p < 0.001$), with the authors concluding that in ACS patients with scheduled PCI, prasugrel therapy was associated with significantly reduced rates of ischemic events, including stent thrombosis, but with an increased risk of major bleeding, including fatal bleeding and probable avoidance in patients with any history of stroke/transient ischemic attack (TIA), body weight <60 kg or age >75 years.

Ticagrelor, an orally active drug that binds "reversibly" to P2Y12, was recently reported in the

PLATO study, where it was compared to clopidogrel.[39] Ticagrelor was associated with a 16% RRR with regard to the primary endpoint — a composite of death from cardiovascular causes, MI, and stroke — but no significant increase in the overall risk of major bleeding.

Glycoprotein IIb/IIIa Inhibitors

Three Glycoprotein (GP) IIb/IIIa inhibitors are currently available for use – tirofiban, eptifibatide and abciximab. The former two are used in patients who may or may not undergo immediate PCI, while abciximab is administered only when patients with ACS are being considered for early PCI. In patients undergoing primary PCI for ACS, abciximab is associated with a reduction in the composite endpoint of death, recurrent MI and target vessel revascularization.[40-42] On the other hand, tirofiban and eptifibatide have not been extensively studied, although mechanistic studies have suggested improved vessel patency.[43, 44]

In a meta-analysis of NSTEACS patients initiated early after admission, GP IIb/IIIa inhibitors reduced death and MI by 9% at 30 days ($p = 0.015$), whereas major bleeding occurred in 2.4% of patients vs. 1.4% of patients receiving placebo ($p < 0.0001$).[45] The analysis also suggested that treatment effect was greater (18% reduction in death and MI) in patients who had elevated troponin levels (9.3 vs. 11.3%, $p < 0.001$) and that GP IIb/IIIa inhibitors, when used in patients who did not undergo revascularization, were of questionable benefit. Based on current evidence, the best practice is to initiate clopidogrel in addition to aspirin and anticoagulant therapy, e.g. UFH, before diagnostic angiography for lower-risk troponin-negative NSTEACS patients, while both GP IIb/IIIa and clopidogrel should be added before angiography for high-risk troponin-positive NSTEACS patients.[30]

As for STEMI patients, evidence for the use of GP IIb/IIIa inhibitors has evolved from 4 recent trials – BRAVE 3, ON TIME 2, HORIZONS-AMI and MULTI-STRATEGY.[46-49] The results of these studies suggest that in the setting of dual antiplatelet therapy with UFH or bivalirudin as the anticoagulant, adjunctive use of a GP IIb/IIIa antagonist can be useful at the time of primary PCI (PPCI) but not as routine therapy. These agents might provide more benefit in selective use, for example, in patients with a large thrombus burden or those who have not received adequate thienopyridine loading.[50]

Antithrombotic Therapies

Despite limited data, UFH continues to be the most common antithrombotic agent in the management of ACS. The use of adjunctive UFH with streptokinase has been controversial, although a meta-analysis showed a reduction in mortality in comparison with placebo.[51] In a meta-analysis of six randomized studies of NSTEACS patients, UFH added to aspirin was associated with a nonsignificant reduction in death or MI (Odds Ratio [OR] 0.67, 95% CI 0.44-1.02; $p = 0.06$).[52]

Limitations of UFH include required monitoring of activated partial thromboplastin time, a variable therapeutic response dependent on age, weight and renal function. In comparison to UFH, Low-Molecular-Weight Heparins (LMWH) have anti-Xa and anti-IIa activity and high bioavailability, provide more consistent anticoagulation (thereby avoiding the need for monitoring), and are associated with lower risk for heparin-induced thrombocytopenia. At least nine randomized trials have compared LMWH directly with UFH (2 involving dalteparin, 1 with nadroparin and 6 with enoxaparin),[53-61] and 5 of 6 trials of enoxaparin have found end point estimates for death or nonfatal MI favoring enoxaparin over UFH with a pooled OR of 0.91 (95% CI 0.83-0.99).[30]

Among 20,479 patients with STEMI receiving fibrinolysis, enoxaparin administered for 4 to 7 days compared with UFH for 48 hours, reduced the risk of death and nonfatal MI at 30 days (9.9 vs. 12%, RR 0.83, $p < 0.001$), with an increase in the risk of major bleeding (2.1 vs. 1.4%, RR 1.53, $p < 0.001$).[62] In NSTEACS, a meta-analysis of trials comparing enoxaparin to UFH reported an overall 9% reduction in death and MI at 30 days, with a greater effect of 20% seen in trials using more conservative management and when time to PCI was greater.[63] In studies where most patients had early angiography, an increase in the risk of major bleeding was also evident in patients receiving enoxaparin in comparison with UFH, with similar rates of death or MI at 30 days and 6 months.[61]

Direct Thrombin Inhibitors

Of the direct thrombin inhibitors (lepirudin, argatroban and bivalirudin), only bivalirudin is US FDA-approved for use in ACS. In an early study of STEMI patients, bivalirudin, a short-acting direct thrombin inhibitor used as an adjunct to streptokinase, was not associated with further reduction in 30-day mortality.[64] However, in the case of PPCI, use of bivalirudin reduced major bleeding in comparison with UFH in combination with a GP IIb/IIIa inhibitor from 8.3 to 4.9% ($p < 0.001$), as well as 30-day cardiac mortality (1.8% vs. 2.9%; $p = 0.03$), total mortality (2.1 vs. 3.1%, $p=0.047$) and net adverse clinical events at both 30 days (9.2% vs. 12.1%; RR 0.76; 95% CI 0.63-0.92; $p < 0.005$; NNT = 34) and 1 year (15.7 vs. 18.3%, HR 0.84; 95% CI 0.71-0.98; $p=0.3$). These results suggest that this agent might be the antithrombotic agent of choice in PPCI.[48] For moderate- and high-risk NSTEACS, bivalirudin showed similar ischemic benefit to UFH or enoxaparin with a GP IIb/IIIa antagonist but with a 47% reduction in the risk of major bleeding (3.0 vs. 5.6%; $p < 0.001$)[65,66] and is an appropriate choice for these patients.

Factor Xa Inhibition

Fondaparinux, a synthetic factor Xa inhibitor, has been found to reduce 30-day death or MI in patients receiving fibrinolysis (10.9 vs. 13.6%; $p < 0.05$) and in those not receiving fibrinolysis (12.2 vs. 15.1%; $p < 0.01$) compared with UFH or placebo.[67] However, in patients undergoing primary PCI, there was no benefit with fondaparinux vs. enoxaparin at nine days for the composite endpoint of death, MI, or refractory ischemia (5.8% fondaparinux vs. 5.7% enoxaparin) and catheter-associated thrombus was reported 3 times more frequently (0.9 vs. 0.3%); [68] however, a 48% reduction in major bleeding (4.1 to 2.2%) was reported ($p<0.0001$). At 30 days and 6 months, however, fondaparinux was associated with a significant reduction in deaths (295 vs. 352, $p < 0.02$ and 574 vs. 638, $p < 0.05$, respectively). Fondaparinux was also associated with significant reductions in death, MI and stroke ($p < 0.007$) at 6 months and catheter-related thrombus was observed to be mitigated by the addition of UFH. Thus, fondaparinux is an appropriate choice in STEMI patients treated with or without fibrinolysis and in patients with NSTEACS, but should not be used with PPCI, pending additional clinical trial information.

In summary, all ACS patients should receive aspirin and clopidogrel/prasugrel and one antithrombin agent (unfractionated heparin, enoxaparin, bivalirudin, or fondaparinux, but not a combination). When there is increased bleeding risk and an invasive PCI strategy is planned, use of bivalirudin is supported. Although evidence also supports additive benefits of GP IIb/IIIa inhibition, such therapy should be deferred until angiographic assessment is complete. Glycoprotein IIb/IIIa inhibition, commenced in the catheterization laboratory rather than soon after admission, has been shown to reduce major bleeding (4.9 vs. 6.1%, $p < 0.01$) with a nonsignificant increase in ischemic events (7.9 vs. 7.1%, $p = 0.13$).[69]

Reperfusion for STEMI (Fibrinolysis vs. PCI)

Expeditious restoration of flow in the obstructed Infarct-Related Artery (IRA) after symptom onset in STEMI is the key determinant of short- and long-term outcomes, regardless of whether reperfusion is achieved by fibrinolysis or PCI (Table 137.6).

Although availability of an interventional cardiologist is a key determinant of whether PCI is the preferred approach, the literature suggests that this approach is superior to fibrinolysis for facilities that can offer PCI.[70] When a composite endpoint of death, nonfatal recurrent MI and/or stroke is analyzed, superiority of PPCI is based principally on evidence that it reduces the rate of nonfatal recurrent MI (Fig. 137.7).[71, 72]

Fibrinolysis

Fibrinolysis can be achieved either by using nonfibrin-specific agents (streptokinase and urokinase) via intravenous infusions or by infusions of fibrin-specific agents (tissue-type plasminogen activator [tPA])[73] that offer a mortality advantage over streptokinase. Bolus-only fibrin-specific agents (refeplase[rPA], tenecteplase [TNK-tPA])[74,75] are also available and these may achieve greater vessel patency in comparison to streptokinase with similar mortality benefit as tPA. Bolus-only agents are also associated with less systemic bleeding than tPA (TNK-tPA).[75]

The earlier the fibrinolysis, the greater the preservation of left ventricular function and reduction in mortality.[76-78] In the ICU setting, where fibrinolysis is readily available, the decision to administer a fibrinolytic is dictated by the availability of an interventional cardiologist, since not all centers are able to provide

TABLE 137.6: Reperfusion strategies for ST-elevation myocardial infarction

I. Fibrinolysis
    a. Intravenous nonfibrin-specific agents, e.g. streptokinase
    b. Intravenous fibrin-specific agents, e.g. tissue-type plasminogen activator (tPA)
    c. Bolus only fibrin-specific agents, e.g. reteplase (rPA), tenecteplase (TNK-tPA)
II. Catheter-based Reperfusion
    a. Primary percutaneous coronary intervention (PCI)
    b. Rescue PCI
    c. Facilitated PCI
    d. Routine PCI after fibrinolysis

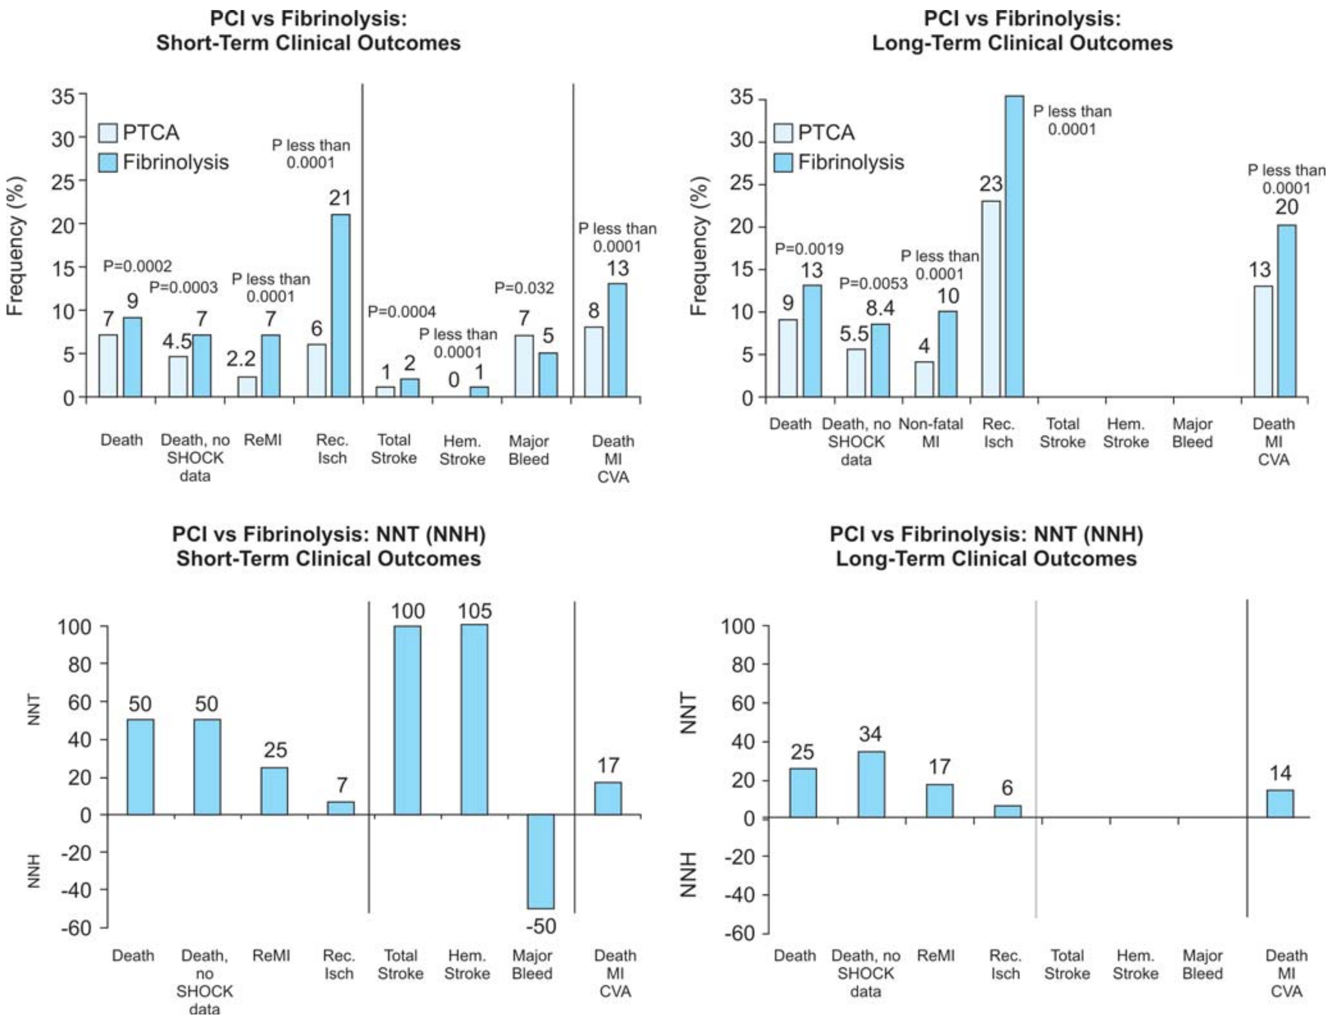

Fig. 137.7: Percutaneous coronary intervention (PCI) vs. fibrinolysis for STEMI. Short-term (4 to 6 weeks; top left) and long-term (top right) outcomes for various endpoints shown are plotted for STEMI patients randomized to PCI or fibrinolysis for reperfusion in 23 trials (n = 7739). Given the frequency of events for each endpoint in the two treatment groups, the Number Needed to Treat (NNT) or Number Needed to Harm (NNH) is shown for the short-term (bottom left) and long-term (bottom right) outcomes. The magnitude of treatment differences for death, nonfatal reinfarction and stroke varies depending on whether PCI is compared with streptokinase or a fibrin-specific lytic agent. For example, when primary PCI is compared with alteplase and the SHOCK trial is excluded, the mortality rate is 5.5 vs. 6.7% (odds ratio 0.81, 95% confidence interval 0.64-1.03, p = 0.081)

PTCA = Percutaneous Transluminal Coronary Angioplasty; ReMI = Recurrent MI; Rec. Isch = Recurrent Ischemia; Hem. Stroke = Hemorrhagic Stroke; CVA = Cerebrovascular Accident.

(From Keeley EC, Boura JA, Grines CL. Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: A quantitative review of 23 randomized trials. Lancet. 2003; 361:13-20. Reproduced with permission from Elsevier.)

24-hour coverage of a catheterization laboratory. Catheterization laboratory staff may also not be readily available during off hours and weekends. While clinical decision-making is under way regarding the use of a fibrinolytic, it augurs well to pay consideration to the contraindications of fibrinolysis (Table 137.7).

Catheter-Based Reperfusion Strategy

Primary PCI has been compared with fibrinolysis in several randomized clinical trials,[79-99] and in the SHOCK trial,[100] which compared medical stabilization to immediate revascularization for cardiogenic shock. This wealth of information has demonstrated that PCI-treated patients experience lower short-term mortality (7 vs. 9%, $p = 0.002$), less nonfatal reinfarction (3 vs. 7% $p < 0.0001$) and less stroke (1 vs. 2%, $p = 0.0004$) than those treated by fibrinolysis.[71,72] This benefit of PCI over fibrinolysis is evident when patients are treated early after symptom onset and increases with greater delay in presentation.[101] The benefit of PCI over fibrinolysis remains dependent

TABLE 137.7: Contraindications to the use of fibrinolysis in STEMI

Absolute	*Relative (Cautious Use)*
1. Any prior ICH	1. Uncontrolled hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)
2. Suspected aortic dissection	2. Recent internal bleeding (within 4 weeks)
3. Active bleeding (excluding menstruation)	3. Active peptic ulcer disease
4. Ischemic stroke in past 3 months	4. Pregnancy
5. Known primary or metastatic brain tumor	5. Major surgery within past 3 weeks
6. Known cerebral AVM	6. Prolonged CPR (>10 min)
7. Significant head or facial trauma in past 3 months	7. Ischemic stroke >3 months ago

The above conditions are viewed as an advisory for clinical decision making and are not all-inclusive.
For streptokinase/anistreplase, prior exposure >5 days ago or prior allergic reaction to these agents are also relative contraindications.
Abbreviations: AVM = Arteriovenous Malformation; CPR = Cardiopulmonary Resuscitation; DBP = Diastolic Blood Pressure; ICH = Intracerebral Hemorrhage; SBP = Systolic Blood Pressure.

on timely implementation, and it has been shown that after adjustment for baseline characteristics, time from symptom onset to balloon inflation is significantly correlated with one-year mortality in patients undergoing PPCI for STEMI (relative risk = 1.08 for each 30-minute delay from symptom onset to balloon inflation; p = 0.04).[102.103] Thus, if the expected medical contact-to-balloon time exceeds the expected medical contact-to-needle time by more than 60 minutes, fibrinolytic treatment with a fibrin-specific agent should be considered unless it is contraindicated.[14] This is particularly important when symptom duration is less than 3 hours, but is less important with longer symptom duration when less ischemic myocardium can be salvaged. There is a complex interplay between the patient's age, infarct location and initial delay in presentation and the tolerable delay for achieving the benefit of PPCI over fibrinolysis. This is less important in the hospital setting (e.g. ICU), although symptoms and signs may be masked for several reasons. In general, the improved outcome of PPCI over fibrinolysis is lost earlier in patients younger than 65 years of age and in those presenting within 120 minutes of symptom onset.[104]

Rescue PCI

In patients with failed fibrinolysis, defined as ongoing chest pain and/or failure of ST-segment resolution by more than 50% at 90 minutes after fibrinolysis, rescue PCI (PCI within 12 hours of failed fibrinolysis) can achieve desirable results. In a meta-analysis of 8 trials, rescue PCI was associated with lower rates of death, heart failure and reinfarction at 6 months (29.2 vs. 41%, 11.8 absolute reduction, 95% CI 5-18, p < 0.001) than a conservative strategy of PCI only for recurrent ischemia after fibrinolysis, although rescue PCI was associated with a 3% (95% CI 0-5, p = 0.02) absolute increase in risk of stroke.[105] Percutaneous Coronary Intervention for reinfarction after fibrinolysis is also better than re-administration of fibrinolytics.[106]

Facilitated PCI

Defined as routine emergent PCI after fibrinolysis, facilitated PCI has not been associated with benefits. The ASSENT-4 PCI study[107] of 1,667 STEMI patients reported an increase in composite death, heart failure and shock compared with PPCI alone (18.6 vs. 13.4%, p = 0.005). Similarly, the FINESSE trial showed no benefit of facilitated PCI following half-dose rPA and abciximab compared with PPCI in 2,452 STEMI patients.[108]

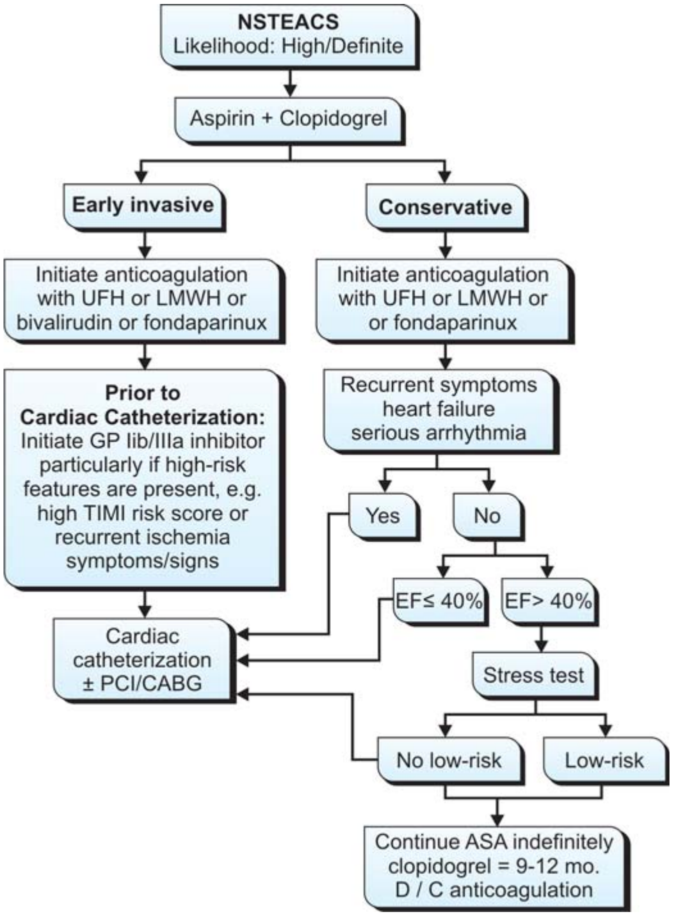
Routine PCI after Fibrinolysis (RPAF)

Defined as early PCI within 24 hours, RPAF could potentially consolidate the benefits of successful fibrinolysis. A meta-analysis of three trials comparing routine PCI with stenting after fibrinolysis to ischemia-guided stenting after fibrinolysis showed a reduction in death of 3.8 vs. 6.7%, (OR 0.56; 95% CI 0.29-1.05, p = 0.07) and a significant reduction in death and MI at 6 months (7.4 vs. 13.2%, p < 0.01). [109] A pharmacoinvasive strategy of immediate fibrinolysis and early revascularization would be practical in many parts of the developing world, where 24-hour access to a catheterization laboratory is not possible.

Reperfusion for NSTEACS

Several studies have explored Routine Invasive Strategy (RIS) versus a Conservative Ischemia-Driven, or "cooling off", Strategy (CIDS) in NSTEACS (Fig. 137.8).[110-115] Two meta-analysis have analyzed this data.[116,117] The first, by

Mehta et al. (n = 9,212), demonstrated a greater rate of in-hospital death or MI with RIS (conservative 3.8 vs. invasive 5.2%; OR 1.36; 95% CI 1.12-1.66, p = 0.002) but a lower rate of these events after hospital discharge (conservative 11.0% vs. invasive 7.4%; OR 0.64; 95% CI 0.56-0.75, p < 0.001). A more recent meta-analysis of studies incorporating randomized controlled trials with higher rates of GP IIb/IIIa inhibitor and clopidogrel use noted a 17% relative reduction in late mortality (OR 0.83, 95% CI 0.72-0.96, p = 0.012) with RIS compared to CIDS. The majority of studies in the past 15 years on this topic have, in general, shown better outcomes with an invasive strategy over medical management, and current debate has now shifted to comparing a strategy of early, routine use of angiography with the less costly alternative of a Selective Deferred Use Strategy (SDUS).[118] Disadvantages of SDUS include the potential for the deterioration of LV function while awaiting coronary angiography and longer delays in or discharge without angiography in the highest-risk patients, such as those with heart failure or renal dysfunction.[119-123]



NSTEACS
Likelihood: High/Definite
Aspirin + Clopidogrel
Early invasive
Conservative
Initiate anticoagulation with UFH or LMWH or bivalirudin or fondaparinux
Initiate anticoagulation with UFH or LMWH or or fondaparinux
Prior to Cardiac Catheterization: Initiate GP IIb/IIIa inhibitor particularly if high-risk features are present, e.g. high TIMI risk score or recurrent ischemia symptoms/signs
Recurrent symptoms heart failure serious arrhythmia

Low-risk
Continue ASA indefinitely clopidogrel = 9-12 mo. D / C anticoagulation

Fig. 137.8: Algorithm for early invasive versus conservative ischemic-driven strategy in patients with NSTEACS. ASA = aspirin; CABG = Coronary Artery Bypass Graft; EF = Ejection Fraction; GP = Glycoprotein; LMWH = Low-Molecular-Weight Heparin; NSTEACS = Non-ST-Segment Elevation Acute Coronary Syndrome; PCI = Percutaneous Coronary Intervation; UFH = Unfractionated Heparin

In general, clinical evidence suggests that early provision of an invasive strategy (within 48 to 72 hours of presentation) is important in achieving lower rates of death or MI in NSTEACS.[124-126] The objective is to provide a strategy with the most potential to yield the best clinical outcome and improved long-term prognosis. Patients with NSTEACS often can be divided into different risk groups on the basis of initial clinical presentation. The TIMI PURSUIT and GRACE scores (Table 137.4) are useful clinical tools for assigning risk to NSTEACS patients, and risk stratification identifies patients who are most likely to benefit from subsequent revascularization. Where clinically appropriate, after considering comorbid conditions, early invasive management of ACS should be implemented as early as possible.

Other Therapies

Oxygen is routinely used in all patients with ACS for at least 24 to 48 hours because of the potential for hypoxemia. Analgesia is important in ACS, since inadequate pain control leads to heightened sympathetic activity, and is usually accomplished with a combination of morphine, nitrates and beta-adrenergic receptor blockers. Morphine, for example, not only is analgesic but also reduces anxiety and helps alleviate autonomic activity, besides achieving a medical phlebotomy in patients with pulmonary edema. Though no randomized trials exist for their use, nitrates are routinely used when managing ACS patients from a pathophysiological standpoint by causing coronary vasodilation and decreasing ventricular preload. There are, however, contraindications in those with inferior wall MI, right ventricular infarction, sustained hypotension (SBP <90 mmHg), and severe bradycardia (<50 bpm), and in patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the last 24 hours (48 hours for tadalafil).

Based on overwhelming evidence,[127] beta-blockers in ACS are recommended routinely and are believed to help in pain relief, reduce infarct size and life-threatening arrhythmias. However, they should be avoided in patients with heart failure (rales greater than 10 cm from the diaphragm), hypotension, severe bradycardia and heart block. Angiotensin-Converting Enzyme (ACE) inhibitors or angiotensin II receptor blockers are indicated in patients with heart failure, anterior infarction, or a history of previous infarction and exert some of their effects in reducing LV remodeling. [128-130] Early initiation of statin

TABLE 137.8: Bird's-eye view of contemporary ACS management

Diagnosis

1. Immediate assessment by physician
2. 12-lead electrocardiogram interpreted within 10 minutes
3. Measurement of serum troponin concentration

Risk Stratification

1. TIMI Score
2. GRACE Score
3. PURSUIT Score

Initial Management

1. Continuous cardiac rhythm monitoring
2. Oxygen therapy
3. Antiplatelet therapy (e.g. aspirin, clopidogrel, prasugrel and/or intravenous glycoprotein IIb/IIIa receptor antagonist)
4. Anticoagulant therapy with enoxaparin, unfractionated heparin or fondaparinux
5. Immediate intravenous and oral β-blockade, if clinical scenario permits
6. Percutaneous coronary intervention, including treatment with a glycoprotein IIb/IIIa receptor antagonist or direct thrombin inhibitor and intracoronary stent implantation
7. Thrombolytic therapy with a fibrin-specific agent
8. Development of local protocols for rapid treatment of patients
9. Rescue percutaneous coronary interventions

Other Interventions

1. Risk stratification using clinical scores and assessment of cardiac function
2. Early pharmacologic intervention with statins, ACE inhibitors, angiotensin receptor blockers and/or aldosterone receptor antagonists

Treatment of Hypoxia and Cardiogenic Shock

1. Noninvasive positive airway pressure ventilation
2. Intravascular volume loading
3. Inotropic therapy
4. Intra-aortic balloon counter pulsation
5. Coronary revascularization
6. Corrective surgery for mechanical complications of acute myocardial infarction

therapy to lower low-density-lipoprotein cholesterol (LDL-C) level to below 100 mg/dl (and preferably to <70 mg/dl) is the preferred approach in ACS, although a meta-analysis of 12 clinical trials with 13,024 patients enrolled soon after ACS found no significant reduction in death, recurrent MI and stroke at 30 days compared with placebo, low-dose statins, or usual care.[131] However, two recent studies utilizing intravascular ultrasound showed that aggressive statin therapy regressed coronary artery disease following ACS,[132] particularly when an Low-Density-Lipoprotein Cholestrol (LDL-C) <70 mg/dl was achieved.[133] These findings support the notion of using even more intensive lipid-lowering therapies post ACS, a notion currently being evaluated in the IMPROVE-IT trial,[134] which is designed to achieve an LDL-C of 50 to 55 mg/dl with the combination of ezetimibe and simvastatin. Although this endpoint approaches the level of LDL-C in newborns, analysis from the PROVE IT-TIMI 22 trial demonstrated continued benefit of intensive lipid lowering among patients with baseline LDL-C values as low as 66 mg/dl.[135,136]

CONCLUSION

Therapeutic options for ACS patients have improved substantially over the past two decades, and our increased understanding of the pathophysiology underlying ACS has also meant a shift in our focus. Biotechnological innovation, such as gene-modulating strategies that favorably affect inflammation, remodeling, oxidative stress and angiogenesis, are being tested in animals and might further change the current framework (Table 137.8) of optimum treatment for patients. However, the largest gains are likely to come from improvements in the effectiveness of our ability to apply these therapies.

Pulmonary Hypertension in the Intensive Care Unit

Neil Ninan, Amber Monson, Arthur Sung

INTRODUCTION

Pulmonary Hypertension (PH) is a rare but debilitating disease that affects individuals of all ages and walks of life. As recently as 15 years ago, a patient diagnosed with PH was given an average survival rate of 2.8 years.[1] Recent advances in treatment options have allowed patients to improve quality and quantity of life. Early diagnosis is essential to slow disease progression.

Pulmonary hypertension is defined as an increase of pressure in the pulmonary arteries where the mean pulmonary artery pressure (mPAP) is $\geq$25 mm Hg. Pulmonary Arterial Hypertension (PAH) has the additional criteria of the pulmonary capillary wedge pressure $\leq$15 mm Hg (Table 138.1). Initial screening for PH is through echocardiography with final diagnosis confirmed through right heart catheterization. Pulmonary hypertension is now considered to have five major classifications with subgroups among each[2,3] (Table 138.2).

TABLE 138.1: Classification of pulmonary hypertension by mean pulmonary arterial pressure (mPAP) into mild, moderate or severe disease

Pulmonary hypertension mPAP $>$25 mm Hg
Pulmonary arterial hypertension wedge $<$15 mm Hg

Mild	25 mm Hg $<$ mPAP $>$ 35 mm Hg
Moderate	35 mm Hg $<$ mPAP $>$ 55 mm Hg
Severe	55 mm Hg $<$ mPAP

Note: Patients with severe right ventricle or atrial dilatation and enlargement may present with lower mPAP due to right sided heart failure.

TABLE 138.2: Classification of pulmonary hypertension according to etiology. The first World Health Organization (WHO) Conference on PH was held in 1973 then again in 1998, 2003. guidelines were most recently assessed at Dana Point in 2008

1. Pulmonary arterial hypertension
    a. Idiopathic
    b. Heritable
    c. Drug/toxin induced
    d. Associated with
        i. Connective tissue disease
        ii. HIV
        iii. Portal hypertension
        iv. Congenital heart disease
        v. Schistosomiasis
        vi. Chronic hemolytic anemia
    e. Pulmonary veno-occlusive disease/pulmonary capillary hemangiomatosis
2. Pulmonary hypertension due to left sided heart disease
3. Pulmonary hypertension due to lung disease and chronic hypoxemia
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension of other mechanisms.

The Intensive Care Unit (ICU) presents a challenging environment for physicians and nurses caring for patients with pulmonary vascular diseases. In the intensive care unit, functional classification and diagnostic testing for etiologies of pulmonary arterial hypertension becomes difficult to perform. Patients are often sedated and mechanically ventilated, thus more thorough investigations similar to outpatient settings are not feasible. In general, clinical groups can be divided into three general categories:

1. Pulmonary venous hypertension
2. Acute onset chronic pulmonary arterial hypertension
3. Newly diagnosed pulmonary arterial hypertension (de novo).

Pulmonary venous hypertension accounts for the majority or two-thirds of the cause of right heart failure.[4] Underlying etiologies include congestive heart failure secondary to systolic and diastolic dysfunction, valvular abnormalities including aortic stenosis, mitral stenosis and mitral regurgitation.[5] Management entails standard of care therapy including preload and afterload reduction and inotropic therapy. In general, invasive hemodynamic monitoring is not required if the diagnosis is clinically compatible. In the remaining of the cases, patients with pulmonary artery hypertension require a different diagnostic and therapeutic approach to improve outcomes.

Pulmonary arterial hypertension is under-diagnosed in the ICU setting as patients are being treated for acute conditions. Quite often, PH is regarded as a secondary diagnosis and clinicians do not treat it aggressively. However, it is known that patients with PH as underlying comorbidity in the ICU have worsened outcomes if untreated.[6] This section will present a few diagnoses that are associated with significant pulmonary arterial hypertension and require more thorough investigations and consideration of advanced therapy. Furthermore, management strategies in the ICU can affect pulmonary vascular tone. Effects from mechanical ventilators and other vasoactive agents will be discussed.

HISTOPATHOLOGY

The pulmonary vasculature is lined by continuous endothelium. The subendothelial layer consists of smooth muscle cell layer that is responsible for modulating vascular tone by systemic and local factors. Over the past decade, signaling pathways and molecules are studied in order to elucidate pathogenesis of PH, as well as their therapeutic potentials (Fig. 138.1).

Nitric oxide (NO), for example, is an important vasodilator and intracellular signaling molecule. NO acts through its cellular mediator, cyclic guanosine monophosphate (cGMP), to induce vascular smooth muscle relaxation and subsequent dilation of the pulmonary vasculature.[7] Dysregulation in its synthesis can lead to vasoconstriction or pathologic hyperproliferation of the vascular endothelium. L-arginine, a precursor in the synthesis of NO, has been used clinically in the treatment of PAH, especially in patients with sickle cell disease to augment vasodilatory effects.[8,9] Other pathways and relevant molecules include arachidonic acid metabolites, prostacycline and thromboxane A2 that affect endothelial and smooth muscle cell functions and platelets aggregation; endothelin-1, a humoral factor that has potent vasoconstrictive properties especially in the pulmonary vascular endothelium.

The histological features of patients with IPAH consist of plexogenic lesions (Figs 138.2A and B). Microscopic examination demonstrates proliferation of the intima and media layers due to muscularization of the arterioles in response to shear stress. Concurrently, there is loss of elastic layers and evident of fibrosis from repair mechanisms.

RIGHT HEART PHYSIOLOGY

The Right Ventricle (RV) is a low pressure and high compliance chamber compared to the left ventricle (LV). With each cardiac cycle, the right ventricle matches the cardiac output of the left heart. Additionally, due to its less muscular conformation, RV ejection is more continuous versus the pulsatile nature of the left ventricle. Similarly, pulmonary capillaries are distensible (high capacitance) such that during exercise, for example, additional blood can be recruited for gas exchange. The pulmonary vascular reserve, therefore, enables marked increase in blood flow before significant resistance is generated, prerequisite condition for the development of pulmonary arterial hypertension.

The primary role of the right heart is to receive returning blood from the systemic venous system and deliver it across the pulmonary vasculature for gas-exchange. The systemic venous return determines the preload, where the driving pressure is the difference between the Mean Systemic Pressure and the Right Atrial Pressure (MAP-RAP). The oxygenated blood enters the left ventricle via post-capillary vasculature or pulmonary venules and veins and is then pumped through the systemic circulation by higher pressures generated by the left ventricle.

Abnormalities involving the pulmonary vasculature leading to an increase in Pulmonary Vascular Resistance (PVR) will lead to right heart strain. The ability of the right ventricle to adapt and compensate for physiologic changes depends on the acuity of the change in PVR, pre-existing right ventricular hypertrophy and its ability to extract, and utilize oxygen in different disease states. Furthermore, the transmural pressure gradient of the right ventricle is dependent upon both systole and diastole, as oppose to the left ventricle, where transmural

perfusion occurs during diastole. Maintenance of adequate mean systemic arterial pressure is an important aspect to be kept in mind especially for intensivists and anesthesiologists caring for critically ill patients.

It is important to recognize that the right ventricle undergoes similar adaptive responses as the left ventricle. Inability to perfuse blood across the pulmonary vascular circuit translates to inadequate left ventricular diastolic filling. Consequently, decrease in left ventricular preload causes inadequate stroke volume and inotropy. Ultimately, this compromises cardiac output to the systemic circulation. The clinical manifestations of right heart failure are peripheral edema, ascites, elevated neck veins and hypotension due to poor LV filling.

Hypertrophy is an appropriate response to RV afterload elevation, i.e. increase in PVR. In patients who cannot compensate for these changes will eventually manifest symptoms of right heart failure or cor pulmonale, as described above. Increases in pulmonary arterial pressure also increase RV afterload, which is a function of the product of RV end-diastolic volume and RV systolic pressure, the Laplace principle of wall tension. Therefore, continual elevation of RV wall stress will eventually cause cor pulmonale and hemodynamic instability. There exists a physiologic relationship among various measured and calculated variables of the right ventricle (Table 138.3). In advanced cor pulmonale, decompensatory changes occur, when the right ventricle

can no longer adequately generate pressures to fill the left ventricle across severely high resistance.

When the right ventricle becomes markedly dilated and hypertropic, the interventricular septum is also mechanically affected and shows systolic flattening (Fig. 138.3). This D-shaped septum is a manifestation of RV pressure overload. An important consequence is interdependence, where LVEDP is elevated due to bulging of the intraventricular septum during systole and clinical manifestations of left heart failure also ensue.

Patients in the intensive care setting are particularly susceptible to factors that can worsen pulmonary pressures. Hypoxia, leading to low alveolar FiO_2, causes hypoxic vasoconstriction that can lead to an increase in PVR. Other factors that exacerbate vasoconstriction include academia and hypothermia. Conditions that increase catecholamine release and sympathetic output such as sepsis and pain or agitation, respectively, will also worsen PVR. It is important to bear in mind that ICU patients have higher metabolic demand and they are particularly sensitive to conditions leading to right heart ischemia. Inadequate, LV filling leading to low cardiac output exacerbates global hypofusion and subsequent metabolic acidosis causes further worsening of PVR and right heart ischemia. Therefore, intensivists should be sensitive to this spiraling cycle and maximize oxygen delivery, and systemic pressures to preserve right heart function.

DIAGNOSTIC MODALITIES

Transthoracic Echocardiography

Acutely ill patients transferred to intensive care units are often too unstable for the comprehensive diagnostic modalities employed to diagnose disease, such as right heart catheterization in the laboratory. For patients with suspected pulmonary hypertension and right ventricular decompensation, bedside transthoracic echocardiography (ECHO) is an ideal diagnostic tool given its portability, non-invasive nature, as well as the ability to be repeated frequently. These attributes have positioned echocardiography as the first line modality in the assessment of right ventricular structure and function, and to estimate pulmonary artery pressure.[10,11]

Echocardiography allows clinicians to evaluate cardiac chamber dimensions, interventricular septal motion and tricuspid regurgitant jet velocity. These are important parameters for estimation of pulmonary artery pressure. Additionally, echocardiography can help establish an etiology, such as left heart failure resulting in pulmonary venous hypertension.

Doppler ECHO incorporating bubble contrast via agitated saline can detect intra- and extra-cardiac shunts. A pulmonary artery systolic pressure >40 mm Hg by ECHO is generally regarded as abnormal[12] although overestimation and underestimation of pulmonary artery pressure is frequent.[13] Nevertheless, studies indicate that echocardiographic estimates are a good correlation to actual pulmonary artery systolic pressure.[14] Raymond and collegues found in their investigations that certain parameters seen on ECHO can prognosticate patients to poorer outcomes, i.e. pericardial effusion, right atrial enlargement and septal displacement.[15]

Patient size, difficulty in positioning a critically ill patient and the level of experience of the technician can result in a poor study. This can decrease the ability for diagnosis and prognosticating pulmonary hypertension. For patients who can tolerate the procedure, a transesophageal echocardiogram yields a higher sensitivity and specificity.[16]

Pulmonary Artery Catheterization

Right heart catheterization is the gold standard for the diagnosis of pulmonary hypertension.[17] This is accomplished in the ICU setting by using a pulmonary artery (PA) catheter that is inserted through either the right internal jugular (RIJ) vein, the left subclavian vein, or femoral veins (right preferred). The RIJ is the preferred route of access as the PA catheter may be left in place for continuous monitoring of cardiac pressures. In the ICU setting, the femoral access sites although performed, are not preferred due to increased risk of infection from proximity to groin area.[18-20] Values measured include right atrial pressure (CVP), pulmonary artery systolic and diastolic pressure, and the Pulmonary Capillary Occlusion Pressure (PCOP). A PCOP $\geq$15 mm Hg suggests left sided disease while a PCOP $\leq$15 mm Hg is consistent with pulmonary arterial hypertension. In the instance of an indeterminate range of PCOP, for example, 15 to 18 mm Hg, a left heart catheterization is the only method able to confirm left heart disease or lack thereof. Therefore, collaboration with cardiology is important in this setting.

Cardiac output and cardiac index can be measured by thermodilution method. Although patients with severe tricuspid regurgitation, especially in the PH population, may give erroneous results by thermodilution. Do to this effect, the Fick's method for measuring cardiac output is preferred. The Fick's principle relies on knowing the uptake of oxygen by an organ and the concentration of oxygen in the arterial and venous circulations. Due to the cumbersome nature of calculating oxygen consumption, the Fick's determination uses a fixed value for oxygen consumption allowing one to more easily calculate the cardiac output.

$$CO = O_2\ Consumption/[(Arterial\ O_2) - (Venous\ O_2)]$$

An important calculation during right heart catheterization is pulmonary vascular resistance (PVR) expressed in Wood units. An abnormal value greater than 3 Wood units is consistent with pulmonary hypertension.

Vasodilator Challenge

Vasoreactivity challenge testing is used to differentiate patients with PAH who may benefit from high dose calcium channel blocker therapy in the outpatient setting.[21,22] Therefore, this test is not commonly performed in the ICU. For patients in the ICU on vasopressors a challenge should not be performed as the agents used can lead to systemic hypotension. Three agents are accepted for use in the vasodilator challenge: inhaled nitric oxide, intravenous adenosine and intravenous epoprostenol.[21] The test is considered positive if the mPAP drops at least 10 mmHg and is <40 mm Hg with no decrease in cardiac output after administration of the vasodilator agent.[23]

BIOCHEMICAL MARKERS

Biochemical markers have been used as a means for prognostication in the outpatient setting. Their utility in the acute setting is unclear, especially for patients in the ICU.

Troponins

Serum troponin has been extensively studied as a marker of pulmonary hypertension primarily in disease prognosis. Troponin-T release due to RV myocyte injury was found to be associated with higher heart rates and serum NT-proBNP levels, over six minutes walk distance and mixed venous oxygen saturation.[24] Serum troponin I elevation was shown to be associated with right ventricular pressure overload secondary to pulmonary embolism.[25]

Brain Natriuretic Peptide

As plasma Brain Natriuretic Peptide (BNP) and plasma N-terminal pro-brain natriuretic peptide (NT-proBNP), the biologically inactive form of BNP, are easily reproducible and relatively inexpensive, they have become useful in the assessment of right heart failure.

BNP is secreted from the cardiac ventricles and is commonly used to stratify patients with left heart failure[26] but has also been shown to be increased in right ventricular dysfunction in proportion to the level of compromise in patients with pulmonary hypertension.[27] Leuchte et al. found BNP levels to be inversely correlated to six minutes walk distance and VO_{2max} in patients with idiopathic pulmonary hypertension.[28]

THERAPY

Therapy for patients with PH in the ICU should be aimed at treating underlying causes that lead to cor pulmonale. As discussed earlier, the most common type of PH encountered in the ICU setting is pulmonary venous hypertension. There are many causes of PVH, but passive venous congestion from post-capillary vasculature is the main physiologic cause of right ventricular dysfunction. When clinical and diagnostic testing data are compatible, improving left ventricle compliance and afterload, as well as preload reduction are the primary goals of therapy.

Preload reduction of intravascular volume is the major goal of therapy in the treatment of both left and right heart failure. Pulmonary hypertension can lead to RV failure, which in turn can lead to decreased cardiac output due to under-filling of the left ventricle. Patients with signs of right ventricular failure, i.e. peripheral edema, warrant the introduction of diuresis, along with sodium and fluid intake restriction, to maintain a negative fluid balance. Judicious administration of fluid or blood products should be carefully considered due to right ventricular dysfunction, such as in the setting of sepsis. While fluid restriction and diuresis is the major goal of patients with pulmonary hypertension, the choice of which drug to use is not clear. Most patients are started on a loop diuretic with furosemide being the drug of choice. There is mounting evidence that torsemide may be a more efficacious agent.[29-32]

Patients with an established diagnosis of PAH on appropriate therapy, in general, should not have their PH medication dose adjusted or stopped, unless continuation is felt to be harmful. This is especially important with continuous prostacyclin therapy, as a reduction or discontinuation of IV infusion may cause exacerbation, or rebound pulmonary hypertension, leading to cardiovascular collapse.[33]

Inhalational pulmonary vasodilators should be considered in patients with respiratory failure and/or hemodynamic instability. Inhaled Nitric Oxide (iNO) has been studied extensively for patients with ARDS and refractory hypoxemia.[34] Although effective in the pediatric intensive care population, iNO has not been shown to improve mortality for adult ARDS, despite improvement in oxygenation.[35,36] ARDS will be discussed specifically in a later section. iNO, however, can be appropriate for the acutely unstable PAH patient with hemodynamic compromise.[37,38] The inhalational route and drug absorption is highest in ventilated areas of the pulmonary parenchyma, this optimizes drug delivery while improving ventilation and perfusion matching. On the other hand, continuous intravenous infusion of vasodilators may have significant systemic effects causing hypotension, as well as blunting the hypoxic vasoconstrictive response.

Epoprostenol is a prostaglandin with potent vasodilatory effects and is currently the only therapy with a grade A recommendation for the treatment of class IV pulmonary hypertension.[39] In trials, epoprostenol has been shown to improve hemodynamics and improve six minutes walk distances.[40,41] Intravenous treprostinil, boasting a longer half-life than epoprostenol (>4 hours vs. 6 minutes) was studied for the treatment of class III and IV pulmonary hypertension and found to also improve hemodynamics.[42]

Vasopressors

Vasopressor therapy is indicated in patients with shock, when there is inadequate cardiac output to meet metabolic demands. There are a number of vasopressor agents available in the ICU setting; with different hemodynamic effects on pulmonary vasculature (Table 138.4).

Norepinephrine is a commonly used vasopressor in the intensive care setting. It increases systemic blood pressure through vasoconstriction and a positive inotropic effect on the heart. Although norepinephrine increases the pulmonary arterial pressure to systemic arterial pressure ratio, its effect is less than that of phenylephrine.[43] Furthermore, phenylephrine was shown to worsen right ventricular function, as evidenced by an increase in the right ventricular end-diastolic pressure in patients with chronic pulmonary hypertension.[44]

Dobutamine and milrinone are agents that support inotropic states and in fact may have favorable physiologic effects on reduction of PVR. Dobutamine is a beta-1 adrenoreceptor agonist that causes increased systemic inotropic activity and vasodilation, thereby reducing left ventricular afterload. In animal models, dobutamine induced a dose-dependant decrease in PVR while also decreasing MAP with increases in cardiac output.[45]

Milrinone is a phosphodiesterase III inhibitor which potentiates the effect of cyclic adenosine monophosphate. It has been shown to significantly reduce pulmonary artery pressures in patients with pulmonary hypertension undergoing cardiac bypass and valvular surgery during the perioperative period.[46,47] As with dobutamine, its vasodilatory effects can lead to systemic hypotension. However, it can be used concurrently with vasopressin causing a lesser increase in the PVR than when combined with norepinephrine.[48]

SPECIFIC ICU DIAGNOSIS AND MANAGEMENT ISSUES

Idiopathic Pulmonary Arterial Hypertension

Patients with idiopathic pulmonary arterial hypertension (IPAH) (WHO group 1) admitted to the intensive care unit have poor prognosis. For patients already on continuous treatment with IV prostacyclin therapy, dose changes in the acute setting are neither recommended nor safe. Furthermore, nursing staff should be educated and oriented in managing the patient's pump system or transitioning to the hospital system. Even a minimal interruption of the medication infusion due to void volume in peripheral IV access can elicit significant rebound pulmonary hypertension and potential cardiovascular collapse in some patients.

For patients without a pre-existing diagnosis of IPAH, an echocardiogram is usually the first diagnostic test that detects right heart pressure elevation. It is difficult to differentiate whether right heart strain is due to long-standing undiagnosed pre-existing disease or a primary disease in the ICU setting. The decision to place a PA catheter in patients with primarily right heart dysfunction causing hemodynamic compromise is appropriate in order to of rule out other causes. In the setting of hypotension where the patient cannot tolerate fluid

TABLE 138.4: Vasoactive agents commonly employed in pulmonary hypertension management in the ICU, the receptors they act on, effects on inotropy, chronotropy, PVR, SVR, and dosing ranges

Vasoactive agents						
Medication	*Receptors*	*Inotropy*	*Chronotropy*	*Dose*	*PVR*	*SVR*
Dopamine	Dopaminergic	Vasodilatation		$\leq$5 mcg/kg/min	-	↑
	α=β	Yes	Yes	5-10 mcg/kg/min		
	α>β	Vasoconstriction		>10 mcg/kg/min		in α range
Dobutamine	β_1 & β_2	Yes	Yes	2-20 mcg/kg/min	↓	↓
Norepinephrine	α>β	Yes	+/-	0.03-1.5 mcg/kg/min	↑	↑
Vasopressin	V_1/V_2	Vasoconstriction		0.01-0.04 units/min	↓	↑
Differing Results						
Phenylephrine	α	No	No	0.05-8 mcg/kg/min	↑	↑
Milrinone	Phosphodiesterase-3	Yes	Yes	0.375 mcg/kg/min	↓	↓

resuscitation, i.e. rising CVP with worsening cardiac index, vasoactive agents should be instituted.

Initiation of continuous IV therapy needs to be performed with caution, as $\dot{V}/\dot{Q}$ mismatch and hypoxemia can ensue with nonselective vasodilatation in patients with concurrent primary respiratory disorders. Inhalational therapy, such as nitric oxide or prostacyclin, can be advantageous in this setting, as the drug is being delivered to vasculature coupled with alveolar units that are functional and thus maintaining $\dot{V}/\dot{Q}$ matching relationship.

Connective Tissue Related PH

Vasculopathies associated with connective tissue disease, such as scleroderma, are a significant contributing factor especially for patients in the ICU. Rheumatology consultation should be sought for a complete management plan in these patients. Pharmacotherapy for these patients is similar to IPAH however should transition to advanced therapies soon due to the poor expected outcome of this patient population.[49,50] Concurrent cytotoxic therapy or high-dose steroids may be indicated in patients who have a crisis related to connective tissue disease.[51]

Portopulmonary Hypertension

Portopulmonary hypertension (PoPH) is classified as group 1 disease according to the WHO. Histology of PoPH is similar to IPAH, which is characterized by plexogenic lesions in the vascular endothelium. It is hypothesized that factors including hyperdynamic state with increased shear stress, portosystemic shunting, bacterial translocation and hepatic injury, cause the imbalance between vasoconstrictive and vasodilatory mechanisms affecting vascular tone. Endothelin-1, TNF -alpha and nitric oxide pathways have all been implicated in its pathogenesis.[52,53] Furthermore, in patients with advanced liver disease, which usually lead to a hyperdynamic state, a normal cardiac output may in fact reflect a more advanced state of right heart failure. A cardiac index of 2.5 dyn/second/centimeters[5] seen in these patients is consistent with mild-to-moderate PoPH. Post-transplant survival data largely comes from multicenter liver transplant databases.[54] Advance vascular vasodilator therapy has been used as a bridge to transplantation.

Pulmonary Thromboembolic Disease

Pulmonary Thromboembolism (PTE) is a complication that can be life-threatening if not treated. With acute PTE, where the patient has no previous pulmonary vascular disease, the right ventricle will adapt but cannot generate a significant compensatory response. Therefore, these patients may present with shock secondary to right ventricular failure. This group of patients requires initial fluid resuscitation and vasopressors, similar to circumstances with right ventricular infarction. Thrombolysis therapy should be considered in patients with refractory hypotension and in dire conditions, surgical or catheter directed embolectomy may be required.[55,56] The majority of patients who survive the initial insult achieve complete recanalization and normalization of the right ventricular function.[57-59] However, a small proportion of patients with recurrent subclinical embolism or incomplete thrombolysis, are at risk for chronic thromboembolic pulmonary hypertension (CTEPH).

CTEPH is a disease that begins in the proximal vasculature of the lung. Progressive worsening is propagated by subsequent vascular remodeling and *in situ* thrombosis. Pulmonary pressures in patients with advanced disease can often rise to systemic ranges (mPAP > 65 mm Hg). The only curative therapy is surgical thromboendarterectomy which is performed in select centers with surgical and perioperative expertise.[60] For patients who are not surgical candidates, with more distal disease, limited medical literature has described the use of advanced vasodilator therapy for long-term management.[22]

Acute Respiratory Distress Syndrome

In patients with ARDS, mechanical ventilation is the primary supportive treatment modality. However, positive pressure ventilation has significant and complex interactions with pulmonary vascular mechanics. The current standard of care is to provide low tidal volume with accompanying optimal PEEP to achieve lung protection and provide adequate oxygenation. Due to poor compliance of the lung, the functional residual capacity (FRC) is reduced with alveolar collapse causing intrapulmonary shunting. Therefore, improvement in FRC by the application of PEEP counteracts the derecruitment of alveoli units and reduces intrapulmonary shunting. On the other hand, the opposite effect can lead to increased pulmonary vascular resistance when there is over-distention of the alveolar units, resulting in compression of the capillaries (Fig. 138.4).

The right ventricular filling pressure, as discussed previously, is dependent on systemic venous return. In the setting of positive pressure ventilation, an increased intrathoracic pressure impedes venous return and therefore compromises preload. Additionally, PEEP has

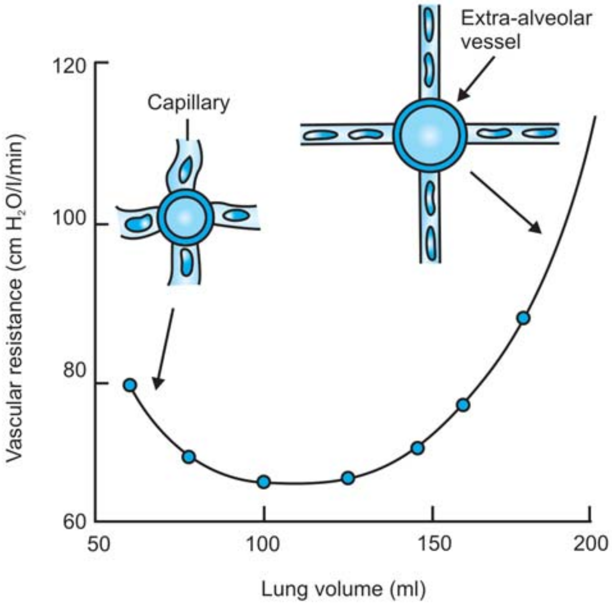

Fig. 138.4: Demonstrates the relationship between pulmonary vascular resistance and lung volumes. Illustrations represent the effects of this relationship on the alveolar vessels

Adapted from: http://rfumsphysiology.pbworks.com/Control-of-Pulmonary-Blood-Flow from JB West, Pulmonary Physiology—The Essential, 7th Edition

multiple effects on right ventricular afterload. While high intrathoracic pressure may worsen PVR by compression of the capillaries, improving oxygenation will also blunt the hypoxic vasoconstrictive response and therefore improve PVR. It behoves the clinician to exercise clinical judgment with ventilator management. Jardin and colleagues have reported a high incidence of right ventricular failure in patients with ARDS.[61] Upto 25% of this patient population manifests cor pulmonale.[62] The outcome is also worsened with greater than three times the likelihood of death.[61] The recommendation for patients with ARDS needing mechanical ventilation management is to be judicious in applying PEEP and limiting the plateau pressure at 30 mm H_2O or less.[63,64]

Perioperative Management

Pulmonologists and intensivists are often requested to evaluate patients in the ICU for perioperative management of PH. It is crucial that close communications are maintained among the consultant, surgeon and especially the anesthesiologist. The preoperative period allows the opportunity to optimize the patient's cardiovascular status. For patients with advanced disease with clinical signs of decompensation, earlier admission to the ICU is reasonable to manage volume status as well as in improving right ventricular function.

There are no clear advantages of performing surgical procedures under general versus local for example, spinal epidural anesthesia. On the other hand, the type and duration of a surgical procedure pose significant impacts on the outcomes of patients with PH. Cardiothoracic and major vascular surgeries entail the highest perioperative risks. More specifically, in cases where patients undergo valvular replacement in order to improve pulmonary venous congestion, cardiac surgery historically has the highest risk of death with advanced disease. In general, for patients with PH associated with severe mitral regurgitation, replacing or repairing the mitral valve can improve pulmonary vascular resistance to a certain extent. Performing a right heart catheterization before and after valvular replacement is indicated for patients who may have significant residual precapillary disease (vascular remodeling) and may benefit from advanced vasodilator therapy.

Certain clinical factors have predictive values for postsurgical outcomes. Patients with functional class III or IV, elevated right atrial pressure greater than 12 mm Hg and reduced cardiac output, confer an increased morbidity and mortality. Ramakrishna and colleagues also described morphologic features on ECHO, such as interventricular septal diastolic flattening and pericardial effusion to be worse predictors.[15]

SUMMARY

Physicians working in the intensive care setting should be knowledgeable in the diagnosis and management of patients with PH. With the advent of advanced therapies, it is essential to understand the vascular physiology and pharmacotherapy, due to co-morbid conditions often existing in this population. Similarly, conditions that can worsen pulmonary vascular resistance, such as increasing airway pressures from mechanical ventilation and metabolic derangements, should be recognized and managed promptly, as decompensation can occur abruptly. Finally, communication and education with other clinicians and specialists is essential to ensure optimal outcomes of patients with this complex disease.

Pediatric Critical Care

Ali M Nadroo, Nitin P Ron, Pramod Narula

INTRODUCTION

After birth, lungs of a neonate undergo a change that involves a transition from fetal to neonatal circulation and the absorption of the lung fluid. The first few breaths facilitate the drainage of lung fluid and establish Functional Residual Capacity (FRC). The process of the maintenance of the FRC is facilitated by the presence of endogenous surfactant. Thus, surfactant deficiency or its inactivation can lead to decrease in FRC and inadequate gas exchange.

Transition from fetal to neonatal circulation involves decrease in pulmonary resistance as a result of the expansion of lungs, fall in arterial CO_2, rise in pH and O_2, an increase in systemic blood pressure and the closure of ductus arteriosus.[1-3]

The causes of respiratory distress in a neonate include surfactant deficiency, delayed absorption of lung fluid, aspiration of meconium into the lungs and failure of decrease in pulmonary resistance leading to persistent of fetal circulatory pattern. Group B Streptococcal infection is also a leading cause of neonatal respiratory distress.[4-7] Furthermore any anatomical abnormality in the respiratory tract or related structures may also lead to respiratory difficulty.[8]

Significant advances in the understanding of the physiology of premature neonate and the advancement in technology have markedly improved the outcome of these patients. Newer modes of treatment include the use of Inhaled Nitric Oxide (iNO) to lower the pulmonary resistance, High Frequency Oscillatory Ventilation (HFOV), and Extracorporeal Membrane Oxygenation (ECMO).[9]

Lung Fluid: Approximately 30 ml/kg of fluid fills the fetal lung. It contains large amount of chloride, small amounts of bicarbonate and almost no protein. Fetal lung fluid is secreted at 4–5 cc/kg/hr as a result of the active secretion of chloride ions into the pulmonary fluid.[10] The pressure in the trachea exceeds that in the amniotic fluid by about 2 mmHg. Thus amniotic fluid rarely enters the developing lung, except in the circumstances of fetal distress. The lung must clear this liquid soon after birth in order for the fetus to complete the transition from intrauterine to extra uterine life. The process of clearing begins two to three days before birth with a decrease in the rate of secretion of fetal lung liquid. During active labor and delivery, the fetal lung fluid decreases to about 35% of the earlier volume.[11,12] The remaining amount must be absorbed after the birth. When the lungs expand, water moves rapidly from the air spaces into the interstitium, subsequently absorbed by lymphatics and pulmonary blood vessels. Delayed absorption of the pulmonary fluid leads to transient tachypnea of newborn,[13] more common among infants born by a C-section to mothers who did not go into active labor.[14,15]

Clinical Assessment of Respiratory Distress in a Neonate

Clinical signs commonly used to assess the pulmonary function in a neonate are: respiratory rate, retractions, nasal flaring, grunting and cyanosis.[16]

Respiratory Rate: Patients with abnormal elastic and resistive components of the work of breathing tend to adjust their respiratory rate to minimize the work. Thus, in patients with decreased lung compliance, such as Respiratory Distress Syndrome (RDS), respiratory rate is rapid and shallow, whereas patients with increased airway resistance (such as caused by subglottic stenosis) may exhibit respiration that is slower and deeper.

Retractions: The negative intrapleural pressure generated during inspiration is determined by the balance between the force of the diaphragm and the compliance of the lung and the chest wall. The neonatal chest being very compliant, substernal, subcostal, and intercostal retractions are readily seen with relatively small changes in lung mechanics. In neonates with respiratory distress, retractions become more apparent as the lungs compliance decreases. Sever retractions may also indicate the complications of respiratory diseases, such as airway obstruction, misplacement of an endotracheal tube, pneumothorax or atelectasis.

Nasal Flaring: The enlargement of the effective air passage produced by the activation of alae nasi results in the reduction of the resistance. Because newborns are obligatory nose breathers, nasal resistance contributes significantly to the total lung resistance. It is commonly observed in infants with respiratory distress.

Grunting: During normal respiration, the vocal cords abduct during inspiration and adduct during expiration with out producing any sound. In the presence of increased work of breathing, neonates attempt to compensate by closing their vocal cords during expiration there by increasing lung volume that leads to an improved ventilation/perfusion ratio. Expiration through partially closed vocal cords produces the grunting sound.

Cyanosis: Cyanosis reflects the presence of a minimum of 5 g/dl of reduced hemoglobin in systemic capillaries. Peripheral cyanosis is often a manifestation of peripheral vascular constriction in response to low environmental temperature or low cardiac output state. Central cyanosis is always pathological and manifestation of significant hypoxia.

PERSISTENT PULMONARY HYPERTENSION OF THE NEONATE (PPHN)

Because of the high pulmonary vascular resistance prior to birth, blood is diverted away from the lungs through the foramen ovale and the patent ductus arteriosus into the low resistance systemic and placental circulation.[17] After abolition of placental circulation, pulmonary resistance should decrease and allow the increased amount of blood flow to lungs accompanied by, increase in systemic vascular resistance, increase in the left ventricular and left atrial pressure that in turn results in functional closure of the foramen ovale. The ductus functionally closes in the full-term infant by 24–36 hours after birth.

Persistent pulmonary hypertension of the newborn is the result of elevated pulmonary vascular resistance to the point that venous blood is diverted through the ductus arteriosus and foramen ovale away from the lungs into the systemic circulation resulting in systemic arterial hypoxemia. It is essential to rule out cyanotic heart disease that can clinically mimic PPHN. It can be classified into three forms:

i. Primary pulmonary hypertension: No evidence of parenchymal disease with radiographically normal lungs.
ii. Secondary: PPHN associated with parenchymal diseases, such as hyaline membrane disease, meconium aspiration or pneumonia.
iii. PPHN associated with hypoplasia of the lungs and reduction of capillary number—diaphragmatic hernia.

Pathophysiology

Failure of pulmonary vascular resistance to decrease after birth, despite improved alveolar oxygenation, lung expansion and increased systemic resistance results in continuing blood flow through the foramen ovale and ductus arteriosus from right to left. With inability to increase pulmonary blood flow, the arterial oxygen tension falls to very low levels. In order to pump blood to either vascular bed, right heart is subject to a large mechanical load in the presence of high pulmonary (suprasystemic) and systemic resistances. Several mechanisms have been proposed that may lead to persistent pulmonary hypertension:

1. High dose intake of aspirin by mothers near term may lead to the intrauterine closure of the ductus with the redirection of blood flow into the high-resistance fetal pulmonary vasculature may occur.
2. There is pathologic evidence that babies with PPHN have greater thickness of medial muscle in pulmonary arteries than in normal full-term infants. This has been attributed to repeated intrauterine hypoxia that stimulates the hypertrophy of medial smooth muscle that surrounds pulmonary arterioles, resulting in the constriction of vessels to an extreme degree for the long periods of time. This may lead to abnormal responsiveness of the pulmonary vasculature to

hypoxia with an inability to relax after the stimulus for vasoconstriction is removed, i.e. birth asphyxia.

3. Poor regional ventilation and alveolar hypoxia may lead to localized vasoconstriction.
4. Congenital Diaphragmatic Hernia (CDH) or other causes of pulmonary hypoplasia are frequently accompanied by the undergrowth of the pulmonary vascular tree and increased vascular resistance.
5. Nitric oxide, eicosanoids, endothelin leukotrienes, tumor necrosis factor and platelet-activating factors are among some of the vasoactive mediators that play a role in transitional circulation. Alterations in the levels of these substances may lead to pulmonary vasoconstriction.
6. Pathological evidence of platelet-fibrin microthromboembolism has been reported in infants who succumb to PPHN. The mechanical obstruction caused by these microthrombi and vasoconstriction caused by the accompanying released vasoactive mediators may induce pulmonary hypertension.[17]

Diagnosis

Primary PPHN presents in the early postnatal period as cyanosis and tachypnea that closely mimic the presentation of cyanotic congenital heart disease. There may be differential cyanosis between the upper and the lower body. The lung fields are usually clear on a radiograph. The degree of hypoxia is variable and the $PaCO_2$ is normal or low.

Secondary PPHN presents primarily as respiratory distress due to the underlying lung disease. As the lung disease deteriorates and patient needs increasing respiratory support, PPHN becomes apparent. Chest radiograph findings are consistent with the underlying disease.

Echocardiography should be performed to exclude congenital heart disease, determine the pulmonary artery pressure, presence, degree and direction of shunt through the duct and foramen ovale, and right or left ventricular function and output. In both the groups of PPHN, the evidence of tricuspid incompetence may be present.[18-21]

Management

The treatment is aimed at the maintenance of normal arterial levels of oxygen and its delivery to the organs of the body, minimizing pulmonary vasoconstriction. The most potent natural pulmonary vasodilators are oxygen and optimal lung inflation.

Oxygen

Early improvement of alveolar oxygenation with supplemental oxygen in the presence of pulmonary parenchymal disease is particularly useful as it often results in the relaxation of the pulmonary arteries and improved pulmonary blood flow. The PaO_2 should be maintained between 80–100 mmHg. Higher levels of inspired oxygen offer no benefit, but may instead contribute to secondary lung injury.

Conventional Ventilation

This is the mainstay of respiratory support. The ventilatory strategy should be based according to the underlying pulmonary disease, if any. Patients should be well sedated, the term and near term babies even paralyzed to ensure optimal ventilator efficiency. It is often necessary to ventilate with high minute volumes (>300 ml/kg) in order to achieve normal blood gases. Small reductions in minute volume that may occur with retained secretions or minor painful procedures may lead to significant changes in oxygenation.

Sedation

Catecholamines stimulate the alpha-adrenergic receptor release, thereby increase pulmonary vascular resistance. Use of a strong narcotic analgesic, like fentanyl at a dose of 3–8 micrograms/kg/hour can prevent pulmonary vasospasm due to minor variability in oxygenation. Alternatively, continuous infusion of morphine sulfate starting at 10 micrograms/kg/hour and/or bolus or continuous infusion of lorazepam may be used. *Paralysis* is usually achieved with Pancuronium bromide administered every 1–3 hours, intravenously at 0.1–0.2 mg/kg/dose. $PaCO_2$ should be maintained between 35 to 40 mm Hg, lower levels than this may cause cerebral vasoconstriction.[22,23]

High Frequency Oscillatory Ventilation (HFOV)

The best effect of HFOV is seen in babies with underlying severe lung disease. It probably works by allowing better lung inflation and alveolar recruitment.[23,24]

Inotropes

Low ventricular outputs are common in these babies. Low output may reflect the inability of right ventricle to pump blood through the lungs against high resistance, which in turn causes a low left ventricular output. In animal studies, dopamine has similar vasoconstrictor activity on the pulmonary as on the systemic vasculature, so at an empirical level, dobutamine is the preferred inotrope starting at 10 micrograms/kg/min.

Significant increase in ventricular outputs with nitric oxide in term babies has been reported, this may be a more rational approach to circulatory support than inotropes.[17]

Vasodilators

Vasodilators that have been used to treat pulmonary hypertension include tolazoline, prostacyclin, magnesium sulfate and nitric oxide. Tolazoline and prostacyclin have been widely used and both drugs have similar vasodilator effects on the systemic and the pulmonary circulation and may cause systemic hypotension. Prostaglandin I_2 (prostacyclin) one of the major endogenous pulmonary vasodilators, is normally produced by the lung when lung vessels are in a constricted state. Whether PPHN is the result of faulty PGI_2 production is not known. Administration of pharmacologic doses of PGI_2 to babies with persistent pulmonary hypertension has proven successful even when tolazoline failed.

Inhaled nitric oxide, a more specific pulmonary vasodilator has become the therapy of choice in term infants with PPHN. In babies with secondary PPHN, the effects of NO are augmented by HFOV.[25] Inhaled nitric oxide directly activates soluble guanylate cyclase resulting in the increased levels of cyclic-GMP in vascular smooth muscle cells. This results in vascular relaxation by prohibiting myosin protein cross-bridge formation in smooth muscle.[26-28] Extracorporeal membrane oxygenation should be considered only in babies who fail to respond to HFOV and NO. Since the introduction of NO and HFOV, the need for ECMO has declined.[29,30]

APNEA

Apnea in a neonate is defined as the cessation of inspiratory gas flow for 20 seconds, or for a shorter duration if accompanied by bradycardia (heart rate less than 100 beats per minute), cyanosis, pallor or desaturation as observed on pulse oxymeter.

Types of Apnea

Obstructive apnea is characterized by the presence of inspiratory muscle activity without inspiratory airflow where as *central apnea* is defined as the absence of inspiratory muscle activity. An obstructive apnea may be followed by central apnea, thus both types may occur during the same episode; termed as *mixed apnea.*

Apnea of Prematurity: Incidence and severity of apnea in premature infants are both inversely related to gestational age. Approximately 50% of infants of less than 1,500 grams birth weight require either pharmacological intervention or ventilatory support for recurrent prolonged apneic episodes. The peak incidence occurs between five and seven days postnatal age. It usually resolves between 34 to 36 weeks postconceptual age. However, apnea of prematurity has been reported to occur up to 41 weeks of postconceptual age in extremely low birth weight infants.[31,32]

Epileptic Apnea: Neonates can develop apnea during seizures. It may be difficult to distinguish this type of apnea from the one due to other causes. Epileptic apnea is usually accompanied by initial tachycardia followed by bradycardia if seizures are prolonged, where as nonepileptic apnea is frequently accompanied by early bradycardia. Continuous EEG monitoring can also be useful in distinguishing the two types.

Etiology

Apnea of prematurity is the most common cause of apnea in the neonatal intensive care unit. It is a specific diagnosis of exclusion. Other causes should be looked for if the apnea progresses in severity, fails to respond to appropriate therapy, severe episodes occur on the first day of life, or if it appears at a gestational age when it should not occur. Apnea in a term or near term infant in the absence of maternal sedation or hypoxia at birth should raise suspicion of some serious underlying cause.

Several factors that can lead to apnea include cardiac and lung disease, sepsis, neurological disorders (such as intracranial hemorrhage of various types, neonatal seizures, hypoxic ischemic encephalopathy or other disorders that lead to increased intracranial pressure), exposure to various drugs (narcotics, beta-blockers), hypoglycemia, hyponatremia, hypocalcemia or hypercalcemia, acidosis, hypothermia or hyperthermia, hematological (severe anemia), and gastrointestinal factors like NEC or gastroesophageal reflux.

Pathophysiology of Apnea

Developmental Immaturity: More frequent occurrence of apneic episodes in immature infants and decrease in their frequency during the period in which brainstem conduction time of the auditory evoked response shortens with advancing gestational suggests that the immaturity of brainstem control of central respiratory drive may be a contributory factor for the apnea of prematurity.[33]

Sleep State: Rapid Eye Movement (REM) sleep is marked by irregularity of frequency, as well as the depth of breathing. Since REM sleep predominates in the preterm infants, they are prone more frequently to apneic episodes.[34,35]

Immature Response to Peripheral Vagal Stimulation: Stimulation of laryngeal receptors in the adult results in coughing while the stimulation of the same receptors in the premature infant results in apnea. Gavage feeding, aggressive pharyngeal suctioning and gastroesophageal reflux may also induce this reflex apnea.

Chemoreceptor Response: Increased breathing effort and ventilation in response to elevated carbon dioxide level reflects predominantly central medullary chemoreceptor response and to a lesser extent, carotid body chemoreceptor activity. The ventilatory response to increased carbon dioxide is decreased in preterm infant with apnea than in those without apnea, which suggests that abnormal respiratory control may contribute to the causation of apnea.

Adults respond to decreased inspiratory oxygen by a sustained increase in ventilation. In contrast, preterm neonates respond to decrease inspiratory oxygen by initial increase followed by a sustained depression of ventilation, or even apnea. This biphasic response may represent initial peripheral chemoreceptor stimulation followed by the overriding depression of the respiratory center as a result of hypoxia. Progressive decrease in inspiratory oxygen also causes a significant flattening of carbon dioxide response in preterm infants.[36]

Obstructive Apnea: A pause in alveolar ventilation occurs due to the obstruction of airflow within the upper airway, particularly at the level of the pharynx. Because the muscles (genioglossus and geniohyoid) that are responsible for keeping the airway open are too weak in the premature infant, the pharynx tends to collapses from negative pressure generated during inspiration. Neck flexion may worsen this form of apnea.[37,38]

Mixed Apnea: A combination of both types of apnea represent as much as 50% of all episodes.[39]

Monitoring

All newborns less than 34 week gestational age should be monitored for both apnea and bradycardia. An alarm should sound if respiration ceases for more than 20 seconds or if the heart rate drops below 100 bpm. Impedance monitors routinely used in neonatal intensive care units cannot detect obstructive type of apnea because chest movement is present with no airflow. Such apneic episodes may only be detected when the monitor displays bradycardia. Also reflex apnea can lead to bradycardia within the seconds of onset, thus setting off the cardiac alarm 10 to 15 seconds ahead of the apnea alarm.

Management

When the monitor alarms sounds, the infant should be observed for the signs of breathing and skin color. If detected to be apneic, pale, cyanotic or bradycardic*, tactile stimulation* should be provided. If the infant does not respond, *bag and mask ventilation* along with suctioning should be applied. Oxygen saturation should be maintained between 88 to 92% with supplemental oxygen if needed.

Nasal Continuous Positive Airway Pressure (CPAP) of 3–4 cm of water may be needed in patients in whom the apnea is recurrent. CPAP splints the upper airway with positive pressure during both inspiration and expiration, thereby preventing pharyngeal collapse. Its use can reduce the frequency of both obstructive and mixed types of apneas. Other mechanisms include the alteration of the Hering-Breuer reflex, stabilization of the chest wall musculature and elimination of the intercostal inspiratory inhibitory reflex. Extreme degrees of flexion and extension of neck should be avoided. Suctioning of pharynx should be performed cautiously since suctioning itself may stimulate reflexes that lead to apnea. Infant should be evaluated for any underlying cause, so that therapy can be directed accordingly.

Pharmacological Therapy: The most common drugs used to treat the apnea of prematurity are the *methylxanthines* (caffeine and theophylline).

Methylxanthines antagonize adenosine, a neurotransmitter that inhibits the respiratory drive and cause respiratory depression. By blocking inhibition, stimulation of respiratory neurons results in an enhancement of minute ventilation, chemoreceptor sensitivity to CO_2, and cardiac output. Other mechanisms by which methylxanthines may reduce apnea include an improvement of diaphragmatic activity and the stimulation of the respiratory center.

Aminophylline is administered as a loading dose of 5–6 mg/kg (PO or IV infusion over 30 min) followed by a maintenance dose 1.5–2 mg/kg/dose (IV or PO given q8–12 hr) started 8–12 hours after the loading dose to achieve the therapeutic level (6–13 mcg/ml). Plasma half life of aminophylline is about 20–30 hours. Trough level should be obtained at 48–72 hours after loading dose. Levels of >20 mcg/ml are considered toxic.

Aminophylline has a narrower difference between toxic and therapeutic range compared to caffeine.

Caffeine citrate is administered as a loading dose of 20 mg/kg (PO or IV as a single or divided in two doses of 10 mg/kg each) followed by a maintenance dose of 2.5–5 mg/kg/dose (PO/IV Q24 hours), started 24 hours after the loading dose. Therapeutic level of caffeine is seen between 5–25 mcg/ml. Trough level may be obtained on day 5 or 6 after the loading dose.

Since toxic level is greater than 40–50 mcg/ml, there is greater margin of safety routine monitoring of blood levels may not be needed. Caffeine citrate has a longer plasma half-life of 40–230 hours and has fewer side effects. Methylxanthine therapy is usually continued until the infant has reached 32–37 weeks postconceptual age and apneic episodes have ceased. Patients should be monitored for any recurrence of apnea, at least for five days after the medication has been discontinued. Major side effects of methylxanthines are tachycardia, vomiting, feeding intolerance, jitteriness and seizures. Generally the dose is held if heart rate exceeds 180/minute.[40]

Intermittent Mandatory Ventilation (IMV) may be needed, if significant apnea persists despite using both pharmacotherapy and CPAP administration. It has been recently suggested that Nasal Intermittent Positive Pressure Ventilation (NIPPV) is more beneficial than CPAP alone in reducing frequency of apnea of prematurity.[41]

SIDS and apnea of prematurity: Although preterm infants constitute about 18% of all infants with SIDS, only 2 to 4% of SIDS cases had a hospital record of apnea of prematurity. The factors that reduce the risk of SIDS include sleeping on the back, encouraging breast feeding, avoiding exposure to smoking and overheating.[42]

Meconium Aspiration Syndrome

Meconium Aspiration Syndrome (MAS) is defined as respiratory distress in an infant born through Meconium-Stained Amniotic fluid (MSAF) whose symptoms cannot be otherwise explained. It is caused by the aspiration of meconium that may occur in utero or after delivery with the first few breaths. About 13% of all live births are associated by MSAF while only 5% of those born through MSAF develop MAS. MAS accounts for about 1,000 deaths annually in the United States.[43,44]

Pathogenesis

Passage of meconium by the fetus into the amnion fluid does not necessarily indicate fetal distress. It may represent an adaptation reflux developed by a mature fetus with age appropriate levels of motilin in gastrointestinal tract. Cord or head compression also may lead to the passage of meconium through vagal stimulation in the absence of fetal distress. Passage of meconium may also be secondary to an "in utero" stress as a result of fetal hypoxia and acidosis producing relaxation of the anal sphincter. Term and postmature fetuses are more likely to pass meconium in response to such a stress than preterm. Perinatal conditions that increase the risk of MAS include maternal hypertension, diabetes mellitus, heavy cigarette smoking, preeclampsia, eclampsia, intrauterine growth retardation, oligohydramnios and intrauterine hypoxia due to any other cause.

Chronic fetal hypoxia and acidosis may lead to fetal gasping leading to "in utero" aspiration of meconium. Vigorous infant who aspirates meconium-stained fluid from the nasopharynx at birth, usually develops milder form of disease as compared to the severe cases caused by chronic fetal hypoxia.[45]

Mechanisms of Injury

Aspiration of meconium can adversely affect the lung function secondary to partial or complete mechanical obstruction of airways, inactivation of surfactant, vasoconstriction of pulmonary vessels, and chemical pneumonitis.[46] "Ball-valve" effect secondary to partial obstruction leads to air trapping in the alveoli with ventilation and perfusion mismatch and increased risk of air leak syndromes, complete obstruction of the small airways leads to atelectasis. The risk of pneumothorax is estimated to range from 15 to 33%.

Full-term infant with MAS can develop secondary surfactant deficiency due to inactivation that leads to increased surface tension with atelectasis, diminished lung compliance, decreased lung volumes and resultant poor oxygenation. Meconium has a direct inhibitory effect on the function of surfactant and displaces surfactant from the alveolar surface.[47-50] It causes chemical pneumonitis associated with the release of cytokines, such as tumor necrosis factor-α, interleukin-1β, and interleukin-8, may directly injure lung parenchyma or lead to vascular leakage, which causes toxic pneumonitis with hemorrhagic pulmonary edema. Vasoconstriction caused by several underlying factors like hypoxia, acidosis, release of vasoactive mediators like eicosanoids, endothelin-1, and prostaglandin E_2 (PGE_2) may lead to persistent pulmonary hypertension.[47]

Diagnosis

Diagnosis of MAS should be considered in any infant born through MSAF who develops respiratory distress.

The radiographic findings include diffuse, asymmetric patchy infiltrates, consolidation or atelectasis, over aeration leading to air leak syndromes, such as pneumothorax, pneumomediastinum or pulmonary interstitial emphysema.[51] A two-dimensional echocardiogram to evaluate for pulmonary hypertension, may be useful early in an infant's course.

Perinatal Management

MSAF should be considered a possible warning sign of fetal distress. It is recommended that obstetricians should monitor the fetal heart rate tracing and have a low threshold for performing additional testing, such as fetal scalp pH.

Amnioinfusion: It involves infusion of a sterile isotonic solution into the amniotic cavity in order to dilute the meconium. It also increases the volume of amniotic fluid and thereby, decrease the risk of cord compression, which could be a cause for fetal hypoxia and fetal gasping. A recent meta-analysis found a 76% reduction in MAS with amnioinfusion. However, benefits of prophylactic amnioinfusion for MSAF when the fetus otherwise seems well, are not clear.[52-54]

Intrapartum Suctioning: It involves suctioning the mouth, pharynx, and nose as soon as the head is delivered, before the shoulders are delivered in a cephalic presentation or immediately after the head is delivered with a breech presentation. Although intrapartum suctioning has been considered a standard procedure for more than two decades, a multicenter, randomized controlled trial has demonstrated that routine intrapartum oropharyngeal and nasopharyngeal suctioning of term-gestation infants born through MSAF does not prevent MAS.[55-58]

Neonatal Management: The nature of pediatric intervention in infants born through MSAF depends on whether the infant is depressed or vigorous. An infant with a strong respiratory effort, good muscle tone, and a heart rate more than 100 beats/min is defined as vigorous. In such an infant, intubation is not indicated.[59] When an infant is depressed, the upper airway and the oropharynx should be cleared as soon as possible in order to minimize the amount of meconium aspiration. The infant is placed under a radiant heater, drying and stimulating is delayed. Direct laryngoscopy should be performed, mouth and hypopharynx suctioned under direct vision with a 12F or 14F suction catheter, followed by intubation. A negative suction (approximately 100 mm Hg) is directly applied to the endotracheal tube as it is slowly withdrawn. The process may be repeated until no additional meconium is recovered.[56-59] Most infants born through MSAF do not require any intervention and can stay with their mother. However, these infants should be closely monitored for signs of respiratory distress. These infants may exhibit features of postmaturity, such as peeling, yellow staining of skin, long fingernails, and stained umbilical cord. Besides the other signs of respiratory distress, the chest may appear barrel shaped as a result of over inflation. Rales and rhonchi may be heard on auscultation. Most infants who develop symptoms do so in the first few hours of life. Infants at risk for MAS who show signs of respiratory distress, must be transferred to the Neonatal Intensive Care Unit (NICU). The type of respiratory support depends upon the severity of respiratory distress. It varies from simple oxygen hood to mechanical ventilation, iNO and even ECMO. *In sever cases of MAS, a vicious cycle of hypoxemia that leads to acidosis, which together cause pulmonary vasoconstriction and lead to PPHN.* PPHN should be managed as described in section on PPHN.[60]

Surfactant

Use of surfactant in the severe cases of MAS has been demonstrated to decrease the need for ECMO and a possible reduction in the risk of pneumothorax.[50, 60]

Surfactant Lavage: It has been suggested that the use of large-volume lung lavage with dilute surfactant may be effective in removing particulate meconium from the lung, minimize obstruction, and simultaneously offset the inactivation of surfactant by meconium. Its use in the newborn with severe MAS may carry increase in the risks of hemodynamic instability.[61-65]

Inhaled Nitric Oxide (refer to section on PPHN): A large, randomized, multicenter trial has demonstrated that infants with MAS responded better to the combination of iNO and HFOV, possibly because of improved lung inflation and better delivery of nitric oxide to alveoli pretreatment with surfactant may enhance the delivery of iNO to the alveoli, with a resultant increase in oxygenation.[23,65-67]

Extracorporeal Membrane Oxygenation: Infants with MAS make up approximately 35% of those neonates who require ECMO. However, use of iNO for the treatment of PPHN, has markedly reduced the need for ECMO.

RESPIRATORY DISTRESS SYNDROME (RDS)

RDS, also called *hyaline membrane disease,* is the most common cause of respiratory morbidity in neonates. RDS occurs in up to 50% of infants born at 28–32 weeks, the incidence approaches to nearly 100% at 24 weeks.[68,69,70]

Surfactant System: Surfactant is the surface tension lowering substance produced by the alveolar type II cells. It is composed of two main fractions: Lipids and surfactant-specific proteins. Lipids account for 90% and phospholipids form the bulk of the lipids. Other lipids that are found are: Cholesterol, triacylglycerol, and free fatty acids. Phosphatidylcholine (PC) forms 70 to 80% of the total amount of lipid. Approximately 50 to 70% of PC is saturated, especially in the dipalmitoylated form (DPPC). The anionic PG accounts for approximately 8%. Other lipids are phosphatidylethanolamine (PE, ±5%), phosphatidylinositol (PI, ±3%); and phosphatidylserine (PS), lysophosphatidylcholine, and sphingomyelin in small quantities (less than 2%).

About 10% of surfactant consists of four surfactant-associated proteins: The SP-A and SP-D are hydrophilic, and SP-B and SP-C are hydrophobic. Surfactant is stored and exported to the alveolar surface as lamellar bodies. After secretion, surfactant is transformed into specific structures, called tubular myelin, from which phospholipids are inserted into an air-liquid interface, thus reducing the surface tension during expiration. During the next inhalation, surfactant components are lost from the interface and taken back into the type II cell for recycling.[71-75]

Etiology/Pathophysiology

RDS is the result of primary absence or deficiency of surfactant. Without surfactant, the alveoli collapse at the end of expiration. The preterm neonates have both the structural immaturity of the lung, as well as surfactant deficiency.[76-78] Surfactant replacement therapy is the standard of care for preterm neonates suffering from RDS, and has significantly decreased the mortality.

Clinical Features

Surfactant deficiency leads to progressive atelectasis, loss of functional residual capacity, hypoventilation and $\dot{V}/\dot{Q}$ inequality. This, in turn leads to hypoxia, hypercarbia, metabolic acidosis and respiratory failure. It is further complicated in premature infants by week respiratory muscles and compliant chest wall that impair alveolar ventilation. The infants present at birth or within several hours after birth with the signs of respiratory distress that include tachypnea, expiratory grunting, retractions, nasal flaring, cyanosis and increasing oxygen requirement. Other clinical features include pallor, cardiovascular instability, extremity edema that develops after several hours due to altered capillary permeability.

Chest radiographs are characterized by diffuse reticulogranular pattern caused by alveolar microatelectasis, giving the classical ground glass appearance. Aerated bronchioles superimposed on collapsed alveoli give rise to widely distributed air bronchogram. In more severe cases, complete white out of the lungs with the loss of cardiac borders may be seen. Neonatal pneumonia especially caused by group B Streptococcal pneumonia, may present with radiographic features similar to RDS.

The clinical course depends upon the severity of RDS, the gestation age and the birth weight. The uncomplicated clinical course is characterized by the progressive worsening of symptoms with the peak severity by 2–3 days following which recovery begins. When the disease process is severe enough to require assisted ventilation, recovery may take several days or even weeks. However, surfactant therapy may shorten this course.

Clinical Management

S*upportive therapy* constitutes the basic principle of management. Adequate oxygenation, ventilation, temperature and circulation must be assured before the baby is transferred from the delivery room. *Oxygen therapy* by the means of CPAP or positive pressure ventilation is often initiated in the delivery room for the smaller infants, continued in NICU. The infant is placed in thermoneutral environment to reduce oxygen consumption. Close monitoring of vital signs, oxygen saturation, blood gases by noninvasive monitoring and an umbilical arterial line for frequent sampling and accurate blood pressure is often necessary.

Mild or moderate RDS is often managed by *CPAP.* Usually, 3–6 cm of water pressure applied to infant's airways helps to open up the alveoli and prevent atelectasis. Mandatory ventilation should be instituted well in advance of respiratory failure, to avoid hypoxemia, respiratory acidosis and secondary pulmonary vasoconstriction. Pressure cycled ventilators are most frequently used in the NICU, controlled by setting Positive Inspiratory Pressure (PIP), Positive End Expiratory Pressure (PEEP), rate, inspiratory pressure (IT), and FiO_2. Oxygen saturation, PaO_2, $PaCO_2$ and pH should be maintained within the acceptable limits with minimal ventilator parameters to avoid barotraumas and oxygen toxicity to the immature lung. Frequent adjustments are needed in the face of rapidly changing compliance of the lungs after surfactant therapy or during the recovery phase. *Hyperoxia is associated with retinopathy of prematuriy, a leading cause of blindness among premature infants.* PO_2 *is generally maintained between 50 to 80 mm Hg. Hypocarbia of less than 30 mm Hg has been associated with the higher incidence of periventricular leukomalacia.* In severe forms of RDS, non responsive to conventional ventilation and surfactant therapy, use of other modes of ventilation like high frequency oscillation or jet ventilators may be necessary.[79,80,81,82]

Surfactant therapy: Several forms of natural, as well as synthetic surfactant have been used in various regimens. Surfactant therapy appears to decrease the incidence of air leaks, improve oxygenation, and reduce the mortality from RDS among the preterm ventilated neonates. The incidence of Bronchopulmonary Dysplasia (BPD), intraventricular hemorrhage, sepsis and symptomatic PDA seems to be unaltered. Surfactant is administered through the endotracheal tube either through a side-hole adapter connected to an endotracheal tube or a catheter. Dramatic improvement in oxygenation after surfactant therapy correlates well with the improvement in lung volume and stabilization of FRC. If ventilator pressures are promptly lowered, a significant improvement in compliance is seen. The dose is repeated if the oxygen requirement stays more than 30% after 8–12 hours. It is unclear whether a prophylactic dose of surfactant administered intratracheally within the first minutes after birth has any advantage over its use as a rescue therapy after the symptoms have developed. Though earlier therapy has been shown to reduce the need for subsequent treatment, supplemental oxygenation and mechanical ventilation, it should be reserved for infants who need endotracheal intubation and likely to develop a more severe lung disease.

The currently available surfactant preparations are not ideal, require further refinement. Since the role of surfactant proteins in the surface tension lowering function of lipids has been defined, recombinant DNA technology may aid in the production of protein containing surfactant preparations.[78-87]

Prevention of RDS

Although the incidence of premature birth has remained unchanged in the United States, the incidence of RDS has shown a significant decrease at each gestational age. *Use of two doses of antenatal steroids* administered to mother at least 24–48 hours before the birth seems to decrease both the incidence and the severity of RDS. Its effectiveness is enhanced if used prior to gestation of 34 weeks. Although the role of thyroid hormone in lung development and surfactant maturation has been demonstrated in the lung cell culture of humans, subsequent multicenter studies did not show any significant synergistic effect of combined steroid and TRH therapy as compared to steroids alone.[88,89]

SURGICAL DISORDERS PRESENTING AS RESPIRATORY DISTRESS IN A NEONATE

Two to three percent of infants are born with a congenital anomaly that may require intervention soon after birth. Disorders like diaphragmatic hernia, bilateral choanal atresia or hydrops fetalis with pericardial and pleural effusion can be life threatening while other problems like esophageal atresia with tracheoesophageal fistula may present later with aspiration pneumonia. A quick and thorough screening examination for congenital anomalies should be conducted in delivery room.[90]

Choanal Atresia

Choanal atresia is the congenital absence of the posterior nasal aperture (the choanae). It results from the bony fusion or persistence of buccopharyngeal membrane or mixture of both, thus classified as bony, membranous or mixed,[91] unilateral or bilateral. Neonates being obligatory nasal breathers for four to six weeks after birth, bilateral choanal atresia can present as upper airway obstruction leading to respiratory distress and hypoxia. Bilateral choanal atresia presents at birth. The patient becomes cyanotic and struggles for air when quiet, becomes pink while crying.[91, 92]

Unilateral choanal atresia may not be symptomatic. Infants may initially present with foul smelling secretions on the effected side or with respiratory distress associated with upper respiratory obstruction. Inability to pass a 6Fr catheter through the nares into the pharynx suggests the diagnosis. Bilateral choanal atresia is the most common cause of complete upper airway obstruction at birth with an incidence of 1 in 7,000 live births. Twenty to fifty percent of patients with bilateral choanal atresia have associated anomalies that include various syndromes like CHARGE association, Treacher Collins, Aperts, Lenz-Majewski hyperostosis, Antley- Bixler Downs and Crouzon's syndromes.[90-92]

Management at birth depends upon the severity of symptoms and if bilateral or unilateral. *An appropriate oral airway* (size 0 or 00) should be placed and properly secured to prevent dislodging. Thorough *evaluation for other congenital anomalies* should include an echocardiogram, since 70% have associated heart defects.[93,94] CT scan should be performed to differentiate between the bony, membranous and mixed type of choanal atresia.[95]

If patient tolerates oral airway, *surgical correction* may be deferred till 4–6 weeks of age. Immediate repair is recommended if the patient needs endotracheal intubation. *Transnasal endoscopic repair* has been used with better results.[96] Some of the patients may need repeated dilatation in the postoperative period.

Esophageal Atresia

The proximal and distal portions of the esophagus do not communicate, the upper segment is a dilated blind-ending pouch with a hypertrophied muscular and the distal esophageal portion is an atretic pouch with a small diameter and a thin muscular wall. An abnormal communication between the trachea and esophagus may exist and occurs most commonly between the distal esophageal segment and the trachea just above the carina. Esophageal and tracheoesophageal atresia are congenital malformations that are typically diagnosed in neonates within the first few hours of life.[97-101]

Once tracheoesophageal fistula is suspected following steps should be taken in order to stabilize the patient and to *prevent aspiration pneumonia*. *Evaluate for other congenital anomalies* that may have an effect on surgical intervention.[102,103]

Clinical Signs

The inability to swallow and absorb amniotic fluid through the gut leads to polyhydramnios, seen in 95% of infants with Esophageal Atresia (EA) without fistula and in 35% of patients who have EA with a distal fistula.[104-108]

Diagnosis can be made by the inability to pass a large radio opaque (10F) catheter into the stomach. The catheter gets coiled up in the upper pouch and can be seen in posterior-anterior and lateral chest radiographs. Injection of 10 ML of air into the catheter while simultaneously taking an X-ray of the chest and abdomen may outline the pouch. Injection of barium and other contrast materials are not necessary and may pose a risk of aspiration through the fistula.[109,110]

The inability of the infants with esophageal atresia to clear their secretions leads to persistent regurgitation, frothy bubbles in the mouth and sometimes in the nose, drooling and aspiration of secretions. Any attempt at feeding results in choking, coughing, cyanotic episodes and regurgitation of feeds. The reflux of gastric secretions may also occur through the fistula into the tracheobronchial tree and contribute to pneumonia and atelectasis.[100-107]

With atresia alone, the abdomen appears scaphoid. Fifty to seventy percent of children with esophageal atresia may have other anomalies that include vertebral, anorectal, cardiac, tracheal, renal and limb (VACTERL association). Cardiac abnormalities are the most common, especially Ventricular Septal Defects (VSD) and Tetralogy of Fallot (TOF).

The severity of complications after EA repair is often dictated by the extent of the repair required. Primary anastomosis and fistula closure has fewer complications than esophageal replacement. The most common complications include anastomotic leak (14–21%), recurrent fistula, stricture and Gastroesophageal Reflux (GER). Most leaks are small, occur usually after the first 48 hours after surgery, and require only conservative management with the cessation of oral intake and antibiotic therapy. Ninety percent of leaks heal spontaneously. Major anastomotic disruptions occur in only 3 to 5% of leaks, but large leaks can be fatal and require surgical repair. An anastomotic leak can present with choking episodes during feeding and/or recurrent pneumonia. The best methods of diagnosis are bronchoscopy and esophagography. Tracheomalacia is seen postoperatively in almost all patients of tracheoesophageal fistula.[111-116]

Congenital Lobar Emphysema

Congenital lobar emphysema is the result of a group of disorders that lead to the over distention of and air trapping within the alveoli involving a part or whole lobe of a lung. Left upper lobe is most commonly involved (50%), followed by right middle lobe (24%) and right upper lobe (18%). Partial bronchial obstruction has been attributed to defective or overtly compliant cartilage, valve like obstruction created by mucosal folds, bronchial stenosis, and external compression by aberrant blood vessels, mediastinal or intrapulmonary masses. Familial form has also been reported. Males suffer more often than females (1.8:1). About 30% of cases have associated heart anomalies like tetrology of Fallot, ventricular septal defect or anomalous pulmonary venous return.[117-120]

The obstruction is check valve type and progressive distension of the alveoli compress the surrounding normal lung tissue and in some cases, the contralateral lung by crossing over the mediastinum. Patients usually present at 1–2 months of age, but many infants may exhibit symptoms soon after birth or within the first six months of life. Rarely some patients remain undiagnosed up to the school age. Severity of symptoms depends upon the size of the over inflated lobe. Physical findings include hyperresonant note on percussion, decreased breath sound over the affected lobe, and the signs of mediastinal shift.[121,122]

Chest radiograph shows unilateral hyperinflated lobe, bronchovascular markings in the periphery of involved lobe, possibly mediastinal shift and/or atelectasis or collapse of adjacent lobe.[123]

For infants with severe respiratory symptoms, segmentectomy or lobectomy is the treatment of choice. The incidence of complications is low. Asymptomatic patients may not require any definitive treatment. Most respiratory symptoms do not progress, resolve within a year of age. Lobectomy has been successfully avoided in occasional cases by the use of selective endotracheal intubation on the unaffected side or high frequency ventilation.[123,124]

Diaphragmatic Hernia

Congenital Diaphragmatic Hernia (CDH) is characterized by a defect in the diaphragm that occurs due to failure of closure of pleuroperitoneal canal during the sixth to eighth week of gestation. In approximately 85 to 90% of cases, the hernia occurs through the posterolateral lumbocostal triangle, called Bochdalek hernia, whereas 10 to 15% are anteromedial hernias called Morgagni hernia. Bilateral hernia occurs in less than 1% patients, is usually fatal. Left-sided hernia allows the herniation of both small and large bowel, as well as of intra-abdominal solid organs into the thoracic cavity. In right-sided hernias, only the liver and a portion of the large bowel tend to herniate. Depending upon the size of defect, a variable degree of pulmonary hypoplasia is associated with a decrease in the cross-sectional area of the pulmonary vasculature, dysfunction of the surfactant system and increased musculature in the intra-acinar pulmonary arteries. Right-sided hernias may not be symptomatic early because the liver may seal the defect. [119,120,121,125]

CDH occurs in 1/2,000–4,000 live births, isolated posterolateral CDH being 1.5 times frequent in males than females. The risk of recurrence of isolated CDH for future siblings is approximately 2%. Familial CDH has been reported, may be due to a multifactorial or autosomal recessive pattern. As many as 10% of patients with CDH may present after the newborn period, and even during adulthood. Outcome in patients with the late presentation of CDH is extremely good, with low or no mortality.[119,120]

No single gene mutation has been identified as producing or contributing to this anomaly. A variety of chromosomal anomalies, including trisomy 13, trisomy 18, and tetrasomy 12p mosaicism have been reported in 4% of infants with CDH. CDH may be associated with non-chromosomal disorders, such as the de Lange syndrome.[119]

Majority of the patients are diagnosed by an antenatal sonogram. Infants most commonly present with the history of cyanosis and respiratory distress in the first minutes or hours of life, although a later presentation is possible. The infants frequently exhibit a scaphoid abdomen, respiratory distress and cyanosis. In left-sided hernia, auscultation of the lungs reveals poor air entry on the left side. Posterolateral hernia may occur as an isolated defect or in association with other congenital anomalies. CDH can occur as a part of multiple malformation syndrome in up to 40% of infants, principally with cardiovascular, genitourinary, and gastrointestinal malformations. Lethal anomalies are present in up to 16% of infants.[119-121]

Infants with prenatal diagnosis or with symptoms should immediately undergo endotracheal intubation and mechanical ventilation. The resuscitation team should consider the possibility of early pneumothorax if the infant does not stabilize.[122-124,126] High frequency oscillatory ventilation should be considered if high peak inspiratory pressures are needed. Surfactant administration may be helpful because of associated lung immaturity and surfactant deficiency. Inhaled nitric oxide may be used to lower the pulmonary vascular resistance. However, its use has not been shown to reduce mortality or the need for ECMO in infants with CDH. Arterial Blood Gases (ABG) should be monitored frequently because of persistent pulmonary hypertension. Placement of venous and arterial lines is essential because many infants may require the use of inotropic agents, multiple infusions and frequent blood sampling. Associated PPHN should be managed, and patients should be adequately sedated or paralyzed in order to achieve optimal oxygenation. Placement of pulse oxymeter probes at preductal (right-hand) and postductal (either foot) sites may help in assessing a right-to-left shunt at the level of the ductus arteriosus.[125,127-129] ECMO is indicated if optimal oxygenation and perfusion is not achieved by ventilation and medical therapy.

Typical findings in left-sided posterolateral CDH include air- or fluid-filled loops of the bowel in the left hemi thorax and shift of the cardiac silhouette to the right. Due to underlying lung hypoplasia, these patients are prone to the development of pneumothorax. Placement of an orogastric tube prior to the study helps to determine the position of the stomach. *Echocardiogram* should be performed to rule out PPHN and associated cardiac anomalies. If the infant is being considered for ECMO, it is essential to perform cranial ultrasonographic examination to evaluate for intracranial bleeding and anomalies. Patients should also have a renal sonogram.[119,123]

Preoperative stabilization significantly decreases morbidity and mortality. Many surgeons prefer to operate when echocardiographic evidence for normal pulmonary artery pressures is maintained for at least 24–48 hours. Delays of upto 7–10 days are often well tolerated. Surfactant therapy for term infants with a prenatal diagnosis of isolated CDH does not offer any significant benefit.[129] A single lung transplant has been successfully performed. It allows the remaining hypoplastic lung to increase in size and recover from injury while allowing for optimal ventilation and oxygenation.[126,130-132]

ACUTE PULMONARY DISORDERS IN THE PEDIATRIC PATIENT

The pediatric airway differs from the adult airway as it is shorter and narrower, the epiglottis is long and floppy. Therefore, a relatively small amount of airway obstruction can cause significant reduction in airway diameter with increased airflow resistance and work of breathing. Over the last few years, advances have been made in ventilatory management. More recently, ventilatory strategies have involved moving away from mimicking the volumes and pressures of physiologic ventilation, towards using low pressure and low volume strategies, as well as prone position ventilation.[133-138]

Inhaled nitric oxide and extracorporeal membrane oxygenation are now routinely used in the treatment of Persistent Pulmonary Hypertension of the Newborn (PPHN). The outcome figures for pediatric ECMO are not as good as for neonates, with an overall survival rate of 40 to 50%.[139-145] There are recent reports that the use of Volumetric Diffusive Respirator in combination with nitric oxide may have a place in the treatment of respiratory failure unresponsive to conventional modes of treatment.[146]

Croup

The term *croup* refers to a clinical syndrome characterized by barking cough, inspiratory stridor and hoarseness of the voice, also referred to as laryngotracheobronchitis. Most cases of croup are viral in etiology, the most common being parainfluenza virus.

A short history suggestive of a viral upper respiratory infection may be elicited. Subsequently the child develops a hoarse voice, brassy cough and stridor, which is usually inspiratory. The child may appear cyanotic and pale due to hypoxemia—this can eventually progress to respiratory failure.

The steeple sign, which refers to subglottic narrowing of the upper airway, may be evident on radiography.

Management

Mild Croup (no stridor at rest): These children can generally be managed at home, the child should be disturbed as little as possible. Cold mist from a humidifier by the bedside could be more helpful. Treatment of fever, if present, by antipyretics, is also indicated.

Moderate to Severe Croup (Stridor at Rest)

Mist Therapy: Misting through a tent or humidifier has historically been the mainstay of the treatment of croup. However, placing the child in a croup tent may agitate the child and therefore worsen the spasm.

Corticosteroids: Dexamethasone in a dose of 0.15–0.6 mg/kg p.o. or i.m. is recommended. Budesonide, 2 mg by nebulizer, can also be used.[147,148]

Epinephrine: Racemic epinephrine, in a dose of 0.05 ml/kg, to a maximum of 0.5 ml/dose, diluted in normal saline, can be given by nebulization every two hours. Patients requiring more frequent administration of racemic epinephrine should be considered for admission to the pediatric intensive care unit.[149,150]

Intubation and mechanical ventilation should be considered if the child with croup shows the evidence of impending or imminent respiratory failure.

Epiglottitis

Epiglottitis refers to the inflammation of the epiglottis and the supraglottic portion of the airway. This disease has become much less common after the introduction of the Hib vaccine. The commonest causative organism is *H. influenzae*.

The child with epiglottitis may present with a history of high fever, may have a “toxic” look, with drooling, may adopt a “tripod position” sitting with both arms extended and face in the sniffing position. The pharynx should be examined in the operating room by trained personnel ready to intubate. The epiglottis will be seen inflamed and “cherry red” in color.

X-rays may show an enlarged epiglottis, the aryepiglottic folds may be markedly thickened.

The child with suspected epiglottitis should not be agitated or disturbed, this could increase laryngospasm and worsen respiratory distress. Humidified oxygen by mask should be administered if this does not upset the child.

An airway team should be called to the emergency room and should accompany the child to the operating room. Swabs should be taken from the pharyngeal and epiglottic surface, and the child should be intubated under anesthesia and put on mechanical ventilation.[151,152] Tracheostomy may be indicated if the vocal cord edema is severe. Antibiotics, such as ceftriaxone, should be administered for 7 to 10 days.

Bronchial Foreign Body Aspiration

Foreign Body Aspiration (FBA) is a common cause of mortality and morbidity in children, especially in those younger than 2 years of age. A common site for lodgement is the right mainstem bronchus, as it is shorter, straighter and wider than the left mainstem bronchus.[153]

A foreign body lodged in the right mainstem bronchus may cause either partial or complete obstruction. Partial ball valve obstruction, results in overinflation and emphysema of the segment distal to the obstruction, with poor air exchange. If the obstruction is complete, the air in the segment distal to the bronchus, eventually gets absorbed and cause atelectasis. Both of the above situations can lead to secondary infection and abscess formation.

Clinical Features

Immediately after the foreign body is aspirated, there may be paroxysmal coughing. The coughing and wheezing may last for an indefinite period. Reduced air entry on the affected side may be perceived by dullness to percussion. The physical examination may reveal generalized wheezing or localized findings, such as focal monophonic wheezing or decreased air entry. Fever and respiratory distress may develop in the case of superadded infection.

Plain radiographic evaluation of the chest may or may not be helpful in establishing the diagnosis of FBA, depending upon whether the object is radiopaque, and whether the airway obstruction is present. A normal chest radiograph does not rule out foreign body aspiration.

In case of complete foreign body obstruction, chest X-ray may show atelectasis and mediastinal shift to the same side. A radiopaque foreign body may be visualized. In the case of check valve obstruction with emphysema, expiratory films may show mediastinal shift to the side opposite to the obstruction. Rigid bronchoscopy should be done for both diagnosis and management, in case aspiration is strongly suspected. Infection often develops distal to an obstructed airway. Therefore, a consolidated infiltrate is also a possible finding.

Treatment

If in respiratory distress the child should be administered oxygen, and appropriate respiratory support should be provided.

Children, who are symptomatic, with strong suspicion of foreign body aspiration, should be admitted to the hospital. Rigid bronchoscopy should be performed, and the foreign body removed, if visualized. Treatment with antibiotics should be instituted if superadded infection is suspected.

Status Asthmaticus

Asthma is characterized by diffuse, reversible lower airway obstruction with the evidence of inflammation and edema, bronchial smooth muscle spasm and mucous plugging. Some authors characterize a patient with severe asthma as being in status asthmaticus if they fail to respond to at least three doses of nebulizers or bronchodilators.

Clinical Features

Children with acute severe asthma who fail to improve with initial treatment in the emergency department should be admitted to the pediatric intensive care unit. The child will usually present with cough, wheezing and increased work of breathing. Bilateral wheezing may be heard on auscultation, with reduced air entry. However, if air entry is significantly reduced, wheezing may not be heard, a “silent chest” may be an ominous sign.[154] The child may also present in respiratory failure or with cardiopulmonary arrest. The child may have low oxygen saturation on pulse oximetry, may also demonstrate pulsus paradoxus.[155-157]

The diagnosis of status asthmaticus is mainly clinical. Arterial blood gas may show the evidence of respiratory and metabolic acidosis.

Management

Adequate humidified oxygen to keep saturations above 95% should be provided via non-rebreather mask. Albuterol should be administered, either by frequent nebulization or as continuous nebulization. Most studies have used low doses (4 to 10 mg/hr) of continually nebulized albuterol, but recent studies recommend much higher doses (up to 150 mg/hr at 10 to 12 lit/min. flow). Intravenous methylprednisolone (0.5 to 1 mg/kg every 4 to 6 hours), or hydrocortisone (2 to 4 mg/kg every 4 to 6 hours), should be administered. Ipratropium can be used by nebulization in a dose of 250 to 500 micrograms every six hours. Intravenous bronchodilators, such as IV terbutaline in a dose of 0.1 to 10 micrograms/kg/minute should be considered in children unresponsive to continuous nebulization. Some trials suggest using aminophylline, but this remains controversial.[158]

Intravenous magnesium sulfate has been recommended for the treatment of severe asthma (in a dose of 75 mg/kg IV over 20 minutes).[159,160]

Helium-oxygen mixture with a concentration of helium from 60 to 80% can be used.[161,162] However, this cannot be used in children with a relatively high oxygen requirement due to the relatively lower concentration of oxygen in the mixture.[163]

Mechanical ventilation should be avoided, if possible, in patients with severe asthma, as it increases the incidence of complications of barotrauma and air trapping.[164-166] The indications for ventilation include deterioration in the child's mental state, cardiac and respiratory arrest and evidence of severe hypoxia.[167]

Ketamine can be used in children on mechanical ventilation (2mg/kg bolus followed by a continuous infusion of 0.5mg/kg/hr).[168] It should be used with caution in patients with hypercarbia as it may cause increased intracranial tension due to its ability to cause cerebral vasodilatation.[169]

Smoke Inhalation

Smoke inhalation is associated with over half the burn deaths in the US. Advances in technology have been contributing to reducing the mortality due to surface burns.

Injury due to smoke inhalation results due to injury at a cellular level, or due to local or systemic effects. Injury immediately after exposure may be due to the effects of hypoxia or Carbon Monoxide (CO), which causes the poor release of oxygen to the tissues, and may also have a myocardial depressant effect, leading to ventricular arrhythmias.[170] Its effect at the cytochrome oxidase level may cause neurologic manifestations.

The mechanism and effects of smoke inhalation injury may be divided into five phases. Immediate heat transfer may result in severe mucosal injury, acute respiratory distress due to bronchospasm and laryngeal edema. This may go on for 6–12 hours, the bronchospasm may not be reversible by administering β-agonists. In the second phase, from 6–72 hours, pulmonary edema may occur, initially due to increased capillary permeability and subsequently worsened by surfactant deficiency. In the third phase, at two to four days, respiratory distress may occur or be worsened by the presence of a cervical eschar.[171] After two to four days, pneumonia may develop as a result of either restrictive disease or decreased ability of the mucociliary apparatus to clear the airways of bacteria. The late effects of smoke inhalation may be manifest by increased predisposition to airway hyperactivity.[172]

Investigations

In the absence of respiratory signs, early chest films may not be useful in the diagnosis of inhalation injury.[50] Diagnostic bronchoscopy is a useful investigation in evaluating inhalation injury with upto 86% diagnostic accuracy. It has been also used for therapeutic purposes in the presence of atelectasis.[173]

Management

Airway, breathing and circulation should be assessed and appropriately managed. Oxygen 100% through a non-rebreathing mask should be provided. Carboxyhemoglobin levels, blood counts and biochemistry to be sent. Skin burns, if present, should be assessed and managed, and appropriate IV fluids provided.

Asymptomatic, low risk children should be observed for 4 to 12 hours. Severe respiratory distress should be managed with endotracheal intubation and oxygenation. Bronchospasm, if present, can be treated with bronchodilators.

The role of corticosteroids is debatable, their use has been reported to be associated with the increased rate of pulmonary infection.[174] If cyanide toxicity is suspected, antidote in the form of sodium nitrate and sodium thiosulfate should be used. The use of prophylactic antibiotics is controversial. Hyperbaric oxygen has been tried for management of CO poisoning.

Drowning and Near-Drowning

Epidemiology and Definition

Drowning is responsible for about 5,00,000 deaths around the world every year.[175] Drowning is defined as death resulting from suffocation within 24 hours of submersion in a liquid medium, near-drowning is survival atleast 24 hours after an episode of suffocation caused by submersion in a liquid medium. The immersion syndrome is defined as syncope provoked by bradycardia, tachycardia or arrhythmia precipitated by sudden contact with water at a temperature of atleast 5 degrees less than body temperature.

In its 2000 Resuscitation Guidelines, the American Heart Association suggests that the term drowning should refer to a mortal submersion event in which the victim dies within 24 hours, while the term submersion injury should be used up until the time of drowning-related death. In this classification scheme, the term near-drowning is abandoned.[176-178]

Pathophysiology

The pathophysiology of drowning and near-drowning involves hypoxia and metabolic acidosis, and hypercarbia leading to respiratory acidosis.[179] There is initial laryngospasm or breath holding, followed by the aspiration of water. This leads to pulmonary surfactant depletion, alveolar damage, pulmonary edema, intrapulmonary shunting and hypoxia. Ventricular fibrillation may occur due to hypoxia and acidosis, there may be severe peripheral vasoconstriction due to hypoxia, catecholamine release and hypothermia.

Management

Artificial or assisted breaths must be started at the site of rescue of the drowning victim, should not be deferred. Time should not be wasted in trying to extrude the water from the lungs before Cardiopulmonary Resuscitation (CPR) is started. The water would have quickly dissipated into the vascular compartment in case of fresh-water immersion, and would continue to cause fluid to be poured into the lungs (pulmonary edema) in the case of salt-water drowning. Suctioning fluid from the airways may be necessary in the case of salt-water drowning, due to pulmonary edema. Cardiopulmonary resuscitation should be continued as long as needed, until an emergency care facility is reached.[180]

Admission for a minimum of 24 hours is indicated for any drowning victim who was submerged for atleast one minute, was apneic or cyanotic, or required pulmonary resuscitation. Fulminant pulmonary edema despite normal chest X-ray has been reported to develop as long as 12 hours after the episode. Monitoring should be done by serial measurements of blood gases, electrolytes, urea, creatinine and hemoglobin.

Adequate respiratory support should be provided in the form of high-flow oxygen, CPAP or mechanical ventilation, if indicated. Cardiac dysfunction, if present, should be treated with vasopressors, such as dobutamine. Cerebral anoxia and edema should be appropriately monitored and treated. Hyperpyrexia due to the failure of the hypothalamic thermostat has been treated with body cooling, dexamethasone can be used for management of cerebral edema. Any drowning victim should be examined for the presence of cranial and spinal trauma.

Pediatricians, in consonance with parents, children, caregivers and the community must be proactive in implementing the AAP recommendations for the prevention of drowning.[181]

Bronchiolitis

Bronchiolitis is a common viral respiratory infection in children. Respiratory Syncytial Virus (RSV) is responsible for bronchiolitis in over 50% of the cases. Less common causes include parainfluenza virus, human metapneumovirus, influenza virus, adenovirus, coronavirus, and human bocavirus.[182,183] Pathophysiologic processes occur both at the cellular and molecular level. Infection by the virus causes edema and the accumulation of cellular debris, thus causing airway obstruction, air trapping and atelectasis. [184] At a molecular level, cytokines, interleukins and IgE are involved.[185]

Clinical Features

These are often more severe in the younger age groups, especially in the babies of less than 1 year of age. There may be evidence of a mild upper respiratory tract infection with sneezing and rhinorrhea, with or without fever, followed by respiratory distress and wheezing. Very young infants may have apnea. Examination may show the evidence of respiratory distress in the form of nasal flaring, retractions and crackles or wheezing on auscultation. Pulse oximetry may show the evidence of hypoxia. There may not always be a correlation between the degree of respiratory distress and hypoxemia.

Differential Diagnosis

In a younger child, the diagnosis of asthma rather than bronchiolitis may be entertained if there are repeated episodes of wheezing, absence of a viral prodrome and presence of a family history of atopy or asthma. In babies and children presenting with wheezing or stridor, tracheomalacia or bronchomalacia, vascular rings and slings should be ruled out. Pertussis should be entertained as a differential diagnosis in babies with persistent and continuous coughing. Chest X-ray may show the evidence of hyperinflation or atelectasis. Total and differential leukocyte count may be normal or affected. Viral testing can be done by rapid immunofluorescence, this may often avoid the need for sepsis evaluation in an infant.

Management

The management of bronchiolitis is mainly supportive. Babies with significant respiratory distress should be hospitalized, and so should very young infants because of the risk of apnea.[186-188] Cool humidified oxygen should be provided. Oral intake is avoided and parenteral fluids provided if there is risk of aspiration.

Bronchodilators may provide some short-term improvement, although there is little data to support their administration to all patients. Nebulized epinephrine has also been tried as a therapeutic modality, although trials have not shown this to be efficacious.[189-191]

There is little evidence to show that corticosteroids are beneficial, except in the cases of recurrent wheezing where reactive airway disease is the underlying diagnosis.[192]

Ribavirin, an antiviral agent, has been administered by aerosol to infants with chronic lung disease or congenital cardiac disease, but there is no convincing evidence of its efficacy.[193] Respiratory syncytial virus immune globulin has no role in acute bronchiolitis, antibiotics are indicated only in the presence of bacterial pneumonia.[194] Palivizumab, a monoclonal antibody to the RSV F protein, has been effective in reducing the risk of RSV infection before and during RSV season. The latest recommendations for the administration of palivizumab should be followed, which involve monthly intramuscular injections for high-risk groups.[195] Through handwashing is an extremely effective method to prevent nosocomial transmission of RSV.

Mechanical Ventilation: General Principles and Modes

GC Khilnani, Vijay Hadda

INTRODUCTION

Mechanical ventilation is an important method to save life of critically ill patients. In both forms, invasive as well as noninvasive, positive pressure ventilation is widely used worldwide. About one third of adult Intensive Care Unit (ICU) patients receive mechanical ventilation.[1,2] Conceptually, mechanical ventilation is the process to provide O_2 and CO_2 transport between the environment and the alveolar pulmonary capillary interface, with the help of a device. The target of this process is to maintain appropriate PaO_2 and $PaCO_2$ in arterial blood along with reduction in work of breathing. Originally, Mechanical Ventilator (MV) consisted of simple, manually-driven pump device, which over the period has developed into advanced positive pressure ventilator for continuous support of patients in respiratory failure. The earlier MVs delivered fixed volumes or pressures with fixed rates and breath durations, however later advancements allow the patient to trigger the ventilator with their own effort, which can then be cycled-off on time criteria or when certain flow criteria are met.[3] Latest MVs provide many variables, which may be controlled to provide the ventilatory support depending on the underlying disease in an intermittent fashion, mimicking natural breathing. With these advancements, survival rate in patients requiring mechanical ventilation has significantly improved.[4]

An important aspect of mechanical ventilation is a thorough understanding of the equipment being used. There are a wide variety of MVs available for use in the modern pulmonary care. It would be extremely difficult for anyone to master on all the equipment and their functioning. The basic principles and application of different ventilators are similar.

Indications of Mechanical Ventilation

Mechanical ventilation is often used to manage ventilatory or oxygenation failure or an impending failure. Failure to ventilate or oxygenate adequately may be caused by several pulmonary or extrapulmonary conditions, belonging to three distinct groups:

1. *Depressed Respiratory Derive*: This group includes drug overdose (narcotic, sedative, alcohol, etc.), acute spinal cord injury, head trauma, neurologic disorders (coma, stroke, etc.), sleep disorders (e.g. sleep apnea) and metabolic alkalosis.
2. *Excessive Ventilatory Workload*: This group includes acute airflow obstruction, e.g. Chronic Obstructive Pulmonary Disease (COPD), asthma or epiglottitis, dead space ventilation (pulmonary embolism and emphysema), Acute Lung Injury (ALI), e.g. Acute Respiratory Distress Syndrome (ARDS), cardiovascular decompensation (decreased cardiac output, Ventilation/Perfusion ($\dot{V}/\dot{Q}$) mismatch), shock, increased metabolic rate (fever), drugs and decreased compliance (atelectasis, pneumothorax and obesity).
3. *Ventilatory Pump Failure*: This includes chest trauma (flail chest, tension pneumothorax), premature birth (idiopathic respiratory distress syndrome), electrolyte imbalance (hyperkalemia or hypokalemia) and geriatric patients (muscle fatigue).

Phase Variables

The actual factors that provide the four components of a ventilator-delivered breath are called the phase variables. These factors or variables are responsible for changing of one phase of the respiratory cycle into the next and for controlling what occurs during that portion of the breath. The four phases of a breath consists of:

1. Inspiratory phase
2. Change from inspiration to expiration
3. Expiratory phase
4. Change from expiration to inspiration

In each of these four phases a certain variable (time, pressure, volume or flow) is measured and used to initiate, maintain and end the phase.

There are three terms used to describe phase variable:

Triggering of Breath

Triggering is the term applied to the variable that changes from expiration to inspiration.

When a variable, such as time, pressure, volume or flow reaches a preset value and causes the ventilator to change from expiration to inspiration, the ventilator is said to be triggered by that parameter. The ventilator is said to be time-triggered, where inspiration begins when a certain time has elapsed. This occurs independently from a patient's spontaneous effort. In pressure-triggering, the ventilator senses the patient's inspiratory effort sufficient to cause a drop in the baseline airway pressure by preset value and initiates inspiration. The breath occurs regardless of the set rate. It is essential to find the individual patient's need and set sensitivity accordingly, otherwise patient has to either work hard or there will be auto-triggering. A ventilator is said to be flow-triggered, when the baseline flow variable drops below a preset flow and initiate inspiration. Ventilators can also be manually triggered in most cases. This is accomplished by activating the "manual breath" control.

Limiting a Breath

Limiting is a term used to describe the variables that have a limiting value during inspiration or expiration, which could be time, flow or pressure. The length of inspiration is the time from the beginning of inspiratory flow to the start of expiratory flow. During the inspiratory phase, the ventilator can control pressure, volume or flow as described previously in this section. In addition, the ventilator can also limit these variables. Limiting in simple words means the variable can reach the preset value, but never goes higher than it.

Cycling of Breath

Cycling is defined by the preset variable, causing the ventilator to end the inspiration and switch it to expiration. During this process a preset variable (time, pressure, volume or flow) is actually measured by the ventilator, this information is used by the ventilator to determine when to end the inspiratory flow.

Time-cycled ventilation: This is one of the common cycling mechanisms used in clinical practice. Here, time-cycling terminates the inspiratory gas flow and changes to the expiratory phase, when a preselected time interval has elapsed after the start of inspiration. At the designated time, the exhalation valve opens and the delivered Tidal Volume (VT) is vented to the ambient atmosphere. At a constant gas flow and controlled time interval, VT can be predicted according to the following relationship:

Volume = Flow (volume/unit time) × Time

Pressure-cycled ventilation: In this cycling, ventilation terminates the inspiratory phase, when a preselected airway pressure has been achieved. The exhalation valve then opens, initiating the expiratory phase. Tidal volume and the time of active flow delivery will vary in pressure-cycled ventilation, depending on the airway resistance, chest wall and lung compliance and the integrity of the ventilator circuit. As the volume delivery is unpredictable with pressure cycling, this mode is uncommonly used in intensive care settings. They are used predominately for intermittent positive pressure breathing, ventilatory support at home and while using inverse ratio ventilation.

Volume-cycled ventilation: In volume-cycled ventilation, the inspiration is terminated when a preselected volume of gas has been delivered. There is fear of development of excessive airway pressure, in case of airway obstruction therefore, volume-cycled ventilators have pressure-limiting valves that prevent excessive pressure within the system. Without this pressure-limiting valve, excessive pressure may lead to barotrauma.

There has been a belief that volume-cycled ventilation maintains constant VT delivery to the patient, regardless of changes in resistance and compliance. This alleged characteristic is largely responsible for the popularity of these devices in critical care settings. However, the volume of gas received by the patient may vary considerably with volume-cycled ventilation. The variability occurs, since the gas flows into the circuit and the patient. When the ventilator triggers on, its distribution depends on their relative compliance. If there is a decrease in patient's compliance, a larger proportion of the volume is lost within the circuit due to expansion of the tubing and compression of the inspiratory gas within the humidifier or nebulizer, water traps, bellows or cylinder and connectors. Conversely, if the patient's compliance improves, less inspiratory gas is retained within the circuit.

Flow-cycled ventilation: If a preset flow, ends the inspiratory flow, the breath is flow-cycled. Flow-cycled ventilation is independent of airway pressure, VT or duration of inspiration. Flow-cycled mode is most commonly used during pressure support ventilation, in which it is common for the ventilator to cycle into exhalation when the flow during inspiration has dropped to 25% of the peak inspiratory flow.

Patient-Ventilator Interactions

Most of the modern MVs utilize piston or bellow systems of high pressure gas source to drive the gas flow. However, newer MVs provide "interactive" modes, in that patient can interact with ventilator and affect its functions. These interactions can range from simple triggering of mechanical breaths to more complex processes, which can affect various aspects of tidal breath, such as the flow pattern and breath timing.

The patient interacts with ventilator based on three physiological variables:[5]

1. Ventilatory drive when inspiration starts.
2. Ventilatory requirement, i.e. how much flow and volume is required to satisfy the metabolic demand.
3. Timing of the integrated circuits generating the respiratory rhythm, as measured by the duration and ratio of inspiratory time to total breath cycle duration.

Similarly, ventilator interacts with the patient based on three technologic variables:

1. The inspiratory trigger or when the ventilator starts to deliver flow, volume and pressure.
2. The delivery of the gas, i.e. the algorithm used by the ventilator to assist ventilation through delivery of flow, volume or pressure.
3. Cycling or when the ventilator stops assisting the inspiratory effort and lets the patient exhale spontaneously.

Interactive modes allow for muscle activity, which when done at nonfatiguing or physiologic levels may prevent muscle atrophy and facilitate fatigue recovery.[6,7] In addition, permitting spontaneous patient ventilatory activity and using comfortable interactive modes may reduce the need for sedation and/or of neuromuscular blockers, that are often required to prevent patients from "fighting" controlled ventilation.[8]

For the ventilation to be effective, these interactions should be synchronous during different phases of interactive breathe delivery, i.e. breathe triggering, ventilator flow delivery and breathe cycling. Synchronous interactions imply that the ventilator is sensitive to the initiation, modulation and termination of a patient's ventilatory effort. The importance of all these variables has been described below.

Interactions during breath triggering: During interactive mode of ventilation, MVs need to sense a spontaneous effort (a drop in airway pressure or flow change), in order to trigger a mechanical response. Even with modern advanced sensors, there is some unavoidable dyssynchrony in the triggering process due to the artifacts triggering the ventilator (i.e. autocycling) or a certain inherent delay (system responsiveness) in opening of demand valve. Both of these factors can result in a significant work of breathing during the triggering process. In the setting of air trapping and auto-Positive End Expiratory Pressure (PEEP), the elevated alveolar pressure at end expiration can serve as a significant triggering threshold load on the ventilatory muscles. In these circumstances, appropriate use of external PEEP can equilibrate expiratory pressure throughout the lungs and ventilator circuit to reduce this triggering load.[9,10]

Interaction during ventilator-delivered flow: During an interactive breath, ventilatory muscles are contracting.[11,12] At this point of time, the ventilator flow delivery should be adequate to meet one of three goals:

1. Fully unload the contracting ventilatory muscles in patients with severely overloaded and fatigued muscles.
2. Partially unload the contracting ventilatory muscles in patients recovering from muscle fatigue.
3. Add no imposed loads on muscles in patients during spontaneous breathing trials, i.e. Continuous Positive Airway Pressure (CPAP). Synchronous flow interactions are required to achieve these goals.

There is evidence that suggests pressure-targeting breathe, by providing a variable flow, tends to synchronize better with patient effort than the fixed flow pattern of the flow-targeted breath.[13,14] Moreover, a single, consistent assisted or supported breath pattern more readily synchronizes with breath types. Thus, when partial support is desired, Pressure Support/Assist (PS or PA) approach alone appear preferable to Synchronized Intermittent Mandatory Ventilation (SIMV). Although one can argue that SIMV offers the advantage of a guaranteed ventilator rate during partial support, the pressure-assist control mode can similarly, provide both interactive pressure-targeted assisted breaths, as well as backup pressure-targeted controlled breaths.

Interaction during breath-cycling: Cycling dys-synchrony can occur in one of two ways. First, if the breath lasts beyond patient effort, an inadequate expiratory time may develop (along with air trapping) and/or patient expiratory efforts may be required to terminate the breath.[15] Second, if the breath terminates before the patient's effort ends, the patient may be left demanding additional flow without any tidal breathe being delivered by the machine, which significantly imposes loading and/or double breath triggering may result. Cycle dys-synchrony can be addressed by adjusting the tidal volume or inspiratory time in flow/volume-targeted ventilation, by adjusting the inspiratory time in pressure assist-control ventilation or by adjusting the cycle criteria in PS mode of ventilation.

In recent years, certain innovations have been introduced to improve patient-ventilator synchrony during interactive modes of ventilation, such as automatic tube compensation, inspiratory pressure slope and proportional assist ventilation. These have significantly reduced the problem of patient-ventilator dys-synchrony.

MODES OF MECHANICAL VENTILATION

Technological advances have provided a number of different modes, by which a patient can be mechanically ventilated. However, the primary targets are to improve gas exchange, provide patient comfort and speed up weaning from mechanical ventilation. All the ventilators are equipped to deliver either volume-set or pressure-set ventilation. In volume-set ventilation, a preset VT is delivered at whatever pressure it is required. On the other hand, in pressure-set modes, a fixed Inspiratory Pressure (P*insp*) is applied to the respiratory system. Whatever the resulting VT, both usually achieve the same level of ventilation in fully paralyzed patients. In these patients, Plateau Pressure (Pplat) is determined by VT and static Respiratory System Compliance (Crs):

$$\text{Pplat} = \text{VT}/\text{Crs} + \text{PEEP (including auto-PEEP)}$$

Further, VT is predictable (in paralyzed patients), if Crs is known:

$$\text{VT} = (P\textit{insp} - \text{PEEP}) \times \text{Crs}$$

Though the physician's comfort level with volume-set and pressure-set modes may vary, but both modes are similarly tied to each other through the patient's Crs. The potential advantage of pressure-set ventilation is probably greater physician control over the Peak Airway Pressure (P_{rw}) and the Peak Alveolar Pressure (P_{alv}), hence reduction of Ventilator-Induced Lung Injury (VILI). However, could be also attainable with low VT (typically 5 to 8 ml/kg) in volume-set ventilation. Other advantages of pressure-set modes are greater control over inspiratory flow rate and therefore, potentially increased comfort. The disadvantage of pressure-set modes is the increased airflow resistance or lung stiffness, which decreases the minute ventilation. Volume-set modes provide ventilation, but require pressure alarms to detect new abnormalities in respiratory mechanics.

Controlled Mechanical Ventilation (CMV)

The term CMV has been used to describe a volume or pressure-controlled and time-triggered form of ventilation. The operator sets the desired VT (volume controlled) or peak airway pressure (pressure controlled), respiratory rate/frequency (f), Inspiratory Time (TI) and I:E ratio. The patient's ventilation is totally controlled by ventilator and patient cannot trigger the ventilator (Fig. 140.1). However, the controlled ventilation does not guarantee that patient will not attempt to initiate spontaneous ventilation. In such situations, the ventilator will not respond, if it is used strictly in a control mode implying that the ventilator sensitivity is kept "off". This may result in patient-ventilator asynchrony, i.e. the patient attempts to take more breath than the ventilator can provide. It adds to significant patient apprehension, results in CO_2 retention and increased work of breathing. To overcome the problem, the patients need heavy sedation and/or neuromuscular blockade.

The complications observed with use of controlled mechanical ventilation include, excessive ventilation,[16,17] use of sedatives and muscle relaxants,[18] and muscle atrophy resulting from disuse.[19-21] Further, use of heavy sedation/neuromuscular blockade imposes a great risk of apnea/hypoxia in case of accidental ventilator disconnection.

Volume-Controlled (Targeted) Ventilation

Volume-controlled (targeted) mode requires that the operator set a desired VT. Usually, the operator also sets the rate or inspiratory time and gas flow, including flow pattern. During this mode of ventilation, the peak pressure varies from breath-to-breath depending on several factors, primarily patient's lung compliance. However, volume delivered is usually constant.

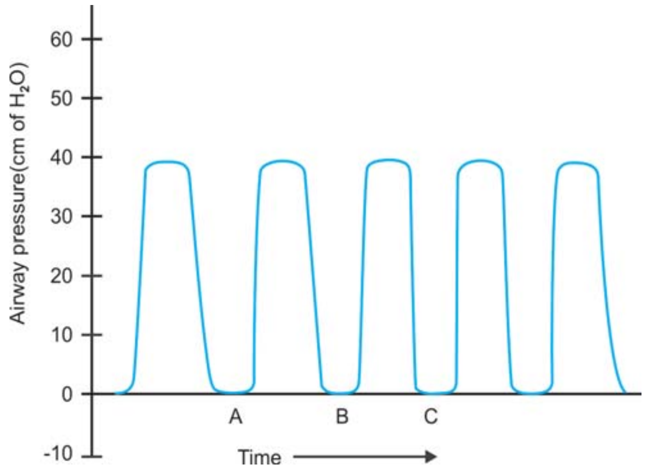

Fig. 140.1: A graphical presentation of CMV

Pressure Controlled (Targeted) Ventilation (PCV)

Pressure controlled ventilation, unlike volume targeted modes, is pressure and time cycled and generates tidal volumes that vary with the impedance of the respiratory system. The ventilation is determined by f, the inspiratory pressure increment (Pinsp-PEEP) and I:E ratio. A working understanding of the factors that determine volume delivery is necessary for proper implementation of this mode of ventilation.

During the inspiratory phase of PCV, gas flows briskly into the ventilator circuit to pressurize the system to a specified target. Once the target pressure has been reached, flow is adjusted to maintain a flat or "square wave" pressure profile over the remainder of the set inspiratory time.[22,23] This is achieved by measuring airway pressure approximately every 2 ms to provide critical feedback to flow controller mechanisms within the ventilator. By tracking the rate of change in pressure during inspiration, appropriate deceleration can occur as the pressure ceiling is approached. Flow is brisk, if the gradient between the circuit pressure and pressure target is large. As in patients without severe obstruction, given a sufficiently long TI, there is equilibrium between the ventilator-determined Pinsp and Palv and inspiratory flow ceases. In such cases, VT can be predicted based on Pinsp (=Palv) and the mechanical properties of the respiratory system (Crs). As the gradient between the recorded pressure and preset target narrows, flow decelerates to prevent overshoot. In situations of severe airflow obstruction or if TI is too short to allow equilibration between ventilator and alveoli, VT will fall below the predicted, based on Pinsp and Crs.

Advantages of PCV: PCV facilitates ventilation with a lung protective strategy. When one of the goals of ventilator management is to limit alveolar overdistention, PCV ensures that Palv never exceeds prefixed threshold value (usually 30 to 35 cm H_2O). Pressure limits and decelerating flow profiles are thought to produce more uniform distribution of forces within the lung, possibly reducing the risk of barotrauma. PCV leads to improved oxygenation, higher static and dynamic compliance along with improved measures of work of breathing. PCV is increasingly used in ARDS patients to deliver Inspiratory Reserve Volume (IRV), in which the TI exceeds the Expiratory Time (TE).

Disadvantage of PCV: PCV, especially when done as IRV, generally requires sedation and sometimes paralysis, which may have adverse effects on weaning.

Assist Control Mode of Ventilation (ACMV)

This is the most commonly used mode of ventilation all over the world. It delivers controlled breaths as well as assists patient triggered breaths. During ACMV, operator can set the inspiratory flow rate ($\dot{V}$), frequency (f) and tidal volume (VT). In some ventilators, one must set the total minute ventilation and rate, thereby determining VT and indirectly determining $\dot{V}$. In fully paralyzed or sedated patients, ACMV behaves like CMV delivering tidal breaths per minute at a operator set rate. Tidal volume and $\dot{V}$, determine the TI, TE and I:E ratio. In turn, Pplat depends on VT and Crs. Patient having their own adequate respiratory effort can trigger the ventilator (Fig. 140.2). During such a breath, the ventilator assists the patient and delivers the set VT at patient's respiratory rate. This ability to trigger extra breaths may change TI, TE, and I:E ratio, may create or increase auto-PEEP. This can be overcome by setting controlled ventilator frequency, a few breaths per minute below the patient's rate, so the control rate serves as an adequate support should the patient stop initiating breaths. If high inspiratory effort continues during the ventilator-delivered breath (few patients may trigger a second or third superimposed/stacked breath), it will lead to breath stacking.

On ACMV mode, patients continue to perform inspiratory work even on ventilator.[7,24] This may not be easily appreciated, despite careful examination of the patient, unless intrathoracic pressures (esophageal pressure or central venous pressure) are measured. Since effort at the end of the breath will affect the Peak Pressure (Ppk) and Pplat, determination of respiratory system mechanics may be unreliable. Clues to patient effort are

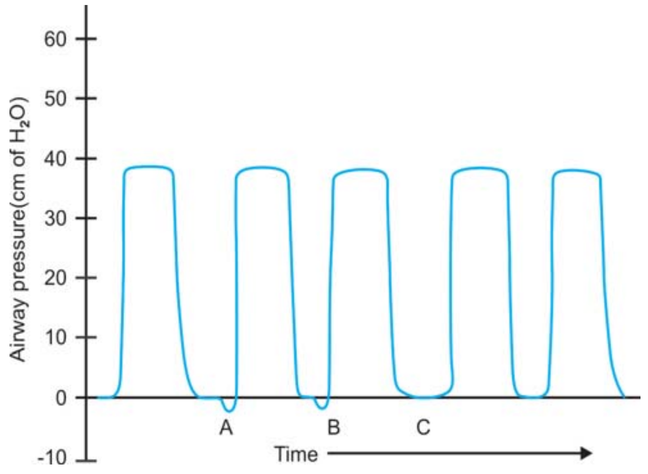

Fig. 140.2: A graphical presentation of Assist Controlled Mechanical Ventilation (ACMV). Each assisted as well as controlled breath, triggers a mechanical ventilator to deliver tidal volume. The assisted breath is characterized by a negative deflection at the beginning of inspiration (breath A and B). While in controlled breathing, there is no negative deflection at the onset of inspiration (breath C)

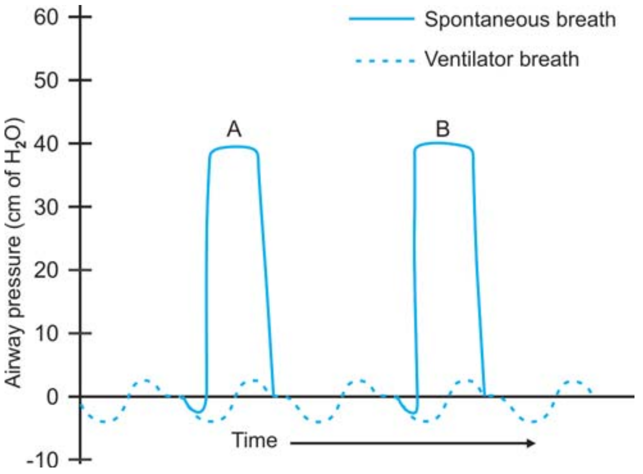

Fig. 140.3: A graphical presentation of Synchronized Intermittent Mandatory Ventilation (SIMV). Tracing is showing two mandatory breaths (A and B) and five triggered breaths. In SIMV the mandatory breaths may be delivered slightly sooner or later (during a small window period) than the preset time, so that the anticipated breath during this is converted into mechanical breath

also often available from the airway pressure tracing (Fig. 140.2). If patient is assisting every breath, the work of breathing can be increased, by either increasing the magnitude of the trigger or by lowering VT. Lowering of "f" at the same VT, generally has no effect on work of breathing.

Indications of ACMV Mode

The ACMV mode is most often used to provide full ventilatory support in the first place. Typically, these patients are having stable respiratory drive (an adequate inspiratory effort of atleast 10 to 12 breaths per minute) and therefore can trigger the ventilator into inspiration. The time-triggering control rate (back up rate) is generally considered as safety net, to provide adequate ventilation in case the patient stops triggering the ventilator. In general, the accepted minimum control rate for ACMV mode is 2 to 4 breaths per minute, lower than the patient's assist rate or a minimum control rate of 12 to 15 breaths per minute.

Advantages of ACMV Mode

There are two advantages of ACMV mode. First, the work of breathing, which is required is minimal when trigger sensitivity is set appropriately and when ventilator supplies adequate flow that meets or exceeds patient's inspiratory demand. Second, if the patient has an appropriate ventilatory drive, this mode allows the patient to control the respiratory rate and hence the minute ventilation.

Complications of ACMV Mode

Alveolar hyperventilation or respiratory alkalosis is the most important complication associated with ACMV mode. Patients on ACMV had higher pH and lower $PaCO_2$, when compared to Intermittent Mandatory Ventilation (IMV).[25,26] This may be an important consideration in patients having inappropriately high respiratory drive/rate due to disease/injury to respiratory center.

Synchronized Intermittent Mandatory Ventilation (SIMV)

SIMV works as CMV in fully paralyzed patients, where ventilation is determined by the mandatory f, VT and V. However in SIMV, if the patient is having breathing effort, he or she may perform respiratory work during the mandatory breaths also. Moreover, the patient can trigger additional breaths, by lowering Airway Opening Pressure (Pao) below the trigger threshold (Fig. 140.3). If this triggering effort comes in a brief, defined interval (synchronization window) before the next mandatory breath is due, the ventilator will deliver the mandatory breath ahead of the scheduled breath, in order to synchronize with the patient's inspiratory effort. If a breath is initiated outside the synchronization window,

V_T, V and I:E ratio are determined by patient's effort and respiratory mechanics, not by ventilator settings. These spontaneous breaths tend to be small and variable from breath to breath. In the absence of breathing effort by the patient, ventilator will deliver a tidal breath with preset V_T and rate. The SIMV mode is often used to gradually augment the patient's work of breathing for weaning. This can be achieved by lowering either the mandatory breath or the V_T. This approach prolongs the process of weaning.[27,28]

Indications for SIMV mode

The primary indication of SIMV is to provide partial ventilatory support, so patient is actively involved in providing part of minute volume. For practical purpose, full ventilatory support is provided usually for the first 24 hours. After this initial period of full ventilatory support, the usual practice of partial ventilatory support, such as SIMV is tried. SIMV have been used for weaning by gradually reducing the rate, but it prolongs weaning, as compared to that with pressure support or spontaneous breathing trial.

SIMV promotes spontaneous breathing and use of respiratory muscles, which results in:

1. Maintenance of respiratory muscle strength and avoids muscle atrophy.
2. Reduced ventilation-perfusion mismatch.
3. Decreased mean airway pressure.
4. Help in weaning. SIMV has inherent property to provide a spontaneous breathing work load that gradually increases patients' muscle strength and endurance. The primary disadvantage is breath wasting, which may occur when patient breathes outside the synchronization window. Although SIMV is commonly used for weaning, this approach prolongs the process of weaning.

Pressure-Support Ventilation (PSV)

Pressure support ventilation is delivered to the mechanically ventilated patient during spontaneous breathing. It is a triggered mode, with changes in airway pressure or flow used as the trigger signal. Ventilation is determined by Pinsp, patient-determined f and patient effort. Following detection of spontaneous patient effort, the ventilator delivers a breath that is flow cycled but time limited. Once a breath is triggered, the ventilator attempts to maintain Pao at the preset Pinsp using whatever flow is necessary. Eventually, flow begins to fall due to cessation of the patient's inspiratory effort, or due to increasing elastic recoil of the respiratory system as VT rises. The termination point is determined by the algorithm within the ventilator, it is usually a function of the delivered tidal volume. At the termination point, inspiratory flow ceases and the breath cycles directly into expiration.

PSV, although is commonly used for weaning purpose, has a potential for providing full ventilatory support. A potential advantage of pressure-support ventilation is improved patient comfort.[29] When a patient is well maintained (on clinical and ABG parameters) at a PS of 5–7 cm of H_2O, it indicate that patient can be extubated.

Patients' own effort is essential for PSV. PSV can account for a large fraction of total minute ventilation, even when set at rather low levels in patients with normal respiratory system mechanics. Old ventilators do not have a back support with PSV, therefore there is risk of apnea/hypoxia. Pressure support ventilation is commonly used for weaning.

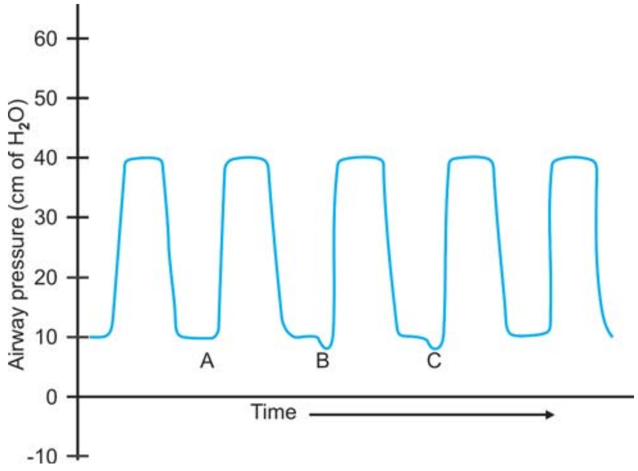

Fig. 140.4: A graphical presentation of Positive End-Expiratory Pressure (PEEP). It is a pressure tracing of assist controlled mode of mechanical ventilation with a PEEP of 10 cm of H_2O. "A" is controlled breath, while "B" and "C" is an assisted breath with PEEP

Positive End Expiratory Pressure

Positive end expiratory pressure increases the end expiratory or baseline airway pressure to a value greater than atmospheric pressure (Fig. 140.4). Positive end expiratory pressure is not commonly regarded as a stand-alone mode, rather it is applied in conjunction with other ventilatory modes. It is used mainly to recruit or stabilize lung units and improve oxygenation in patients with hypoxemic respiratory failure.

Advantages of PEEP

Use of PEEP has positive effects on both the gas exchange and lung mechanics.[30,31] Following are the advantages of PEEP:

Gas Exchange

1. Redistributes fluid within the alveoli and reduces intrapulmonary shunting.
2. Improves arterial oxygenation (PaO_2).
3. Reduces FIO_2 requirement and risk of oxygen toxicity.

Lung Mechanics

1. Helps in preventing alveolar collapse.
2. Stabilizes and recruits lung units.
3. Increases functional residual capacity.
4. Improves lung compliance.
5. Shifts tidal deflections to the right along the inspiratory pressure-volume curve, minimizing potential for ventilator-induced lung injury, by preventing repetitive collapse of lung units at end-expiration followed by reopening during inspiration.
6. May decrease the inspiratory work of breathing due to auto-PEEP in patients with obstructive airway disease.

Indications of PEEP

Indications of PEEP include the respiratory failure due either to intrapulmonary shunting or decreased functional residual capacity, for example, acute lung injury and acute respiratory distress syndrome, cardiogenic pulmonary edema, diffuse pneumonia requiring mechanical ventilation, atelectasis associated with severe hypoxemia and other forms of severe hypoxemic respiratory failure. PEEP is also used in patients with COPD, where there is significant intrinsic PEEP. External PEEP is given approximately at the level of 80% of the intrinsic PEEP. It helps in the easy triggering of breath by counteracting intrinsic PEEP.

Complications of PEEP

The hazards associated with use of PEEP include:

1. Decreased venous return and cardiac output leading to hypotension.
2. Barotrauma.
3. Increased intracranial pressure.
4. Alteration in renal function and water metabolism.

Continuous Positive Airway Pressure (CPAP)

Conceptually, CPAP is not a mode of ventilation, but rather a means of raising functional residual capacity while patient is breathing spontaneousoly. In this mode, ventilatory support is pressure-limited and pressure or flow-triggered, i.e. the spontaneous breath has a pressure limit that remains nearly the same, (within few centimeters of water) during both inspiration and expiration (Fig. 140.5). The patient's inspiratory effort causes the ventilator to increase the flow to the patient to maintain the same pressure during inspiration. During expiration, the flow out of the exhalation valve maintains the expiratory pressure fairly uniform. No mechanical positive pressure breaths are given.

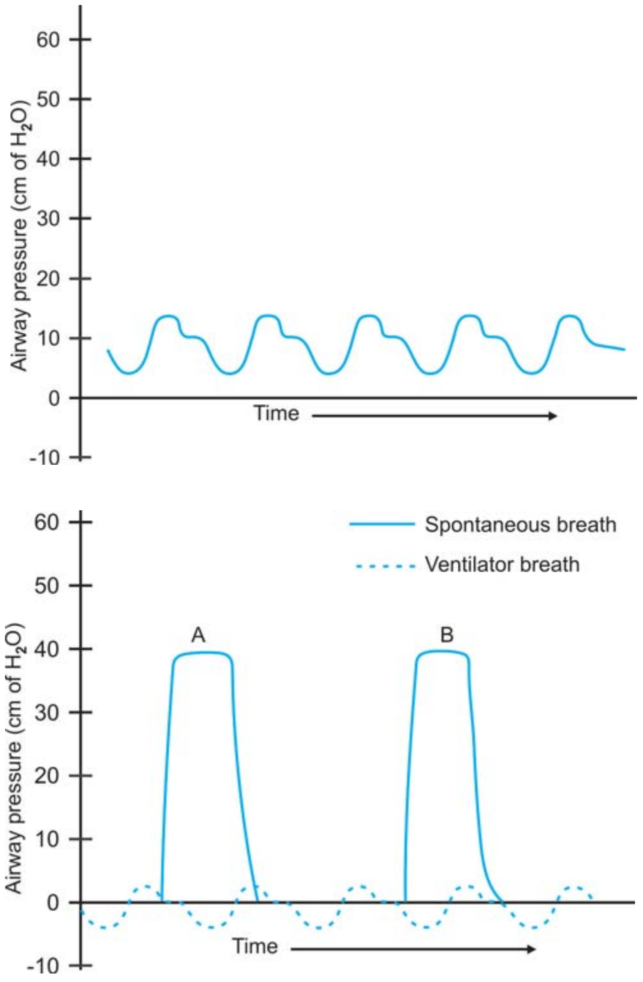

Fig. 140.5: Graphical presentation of CPAP of 14 cm of H_2O

Indications of CPAP

This approach is frequently used to assess the patient's ability to breathe without ventilatory support.
The advantages of CPAP over T-piece breathing are:

1. Improved oxygenation.

2. Detection of low minute ventilation and apnea (as ventilator alarms remain in place).
3. The patient's spontaneous tidal volumes and rate can be easily read.
4. The work of breathing is reduced, if auto-PEEP is present.[32,33]

Bi-Leveled Positive Airway Pressure (Bi-PAP)

Conceptually, Bi-PAP is a mode which combines PEEP with PS and is used more in context of Non-Invasive Ventilation (NIV) using a nasal or oronasal mask. In this mode, both Expiratory Positive Airway Pressure (EPAP) as well as Inspiratory Positive Airway Pressure (IPAP) are adjustable. IPAP helps in improving alveolar ventilation, normalization of $PaCO_2$ and reduction in work of breathing, whereas EPAP improves oxygenation by reducing intrapulmonary shunting. Previously, Bi-PAP was given by dedicated NIV machines. However, majority of the newer ventilators have this facility with inbuilt pressure-controlling valve to maintain a desired EPAP and IPAP levels. Inspiration is triggered at the inspiratory flow of greater than 40 ml/sec for more than 30 milliseconds. Expiratory flow is detected when the inspiratory flow decreases below a manufacturer-determined threshold level (flow cycled) or when IPAP is longer than 3 s (time cycled).

Usual initial setting of EPAP and IPAP are 4 cm of H_2O and 8 cm of H_2O, respectively. Further adjustments are done based on the cardiopulmonary response. If the response is positive, the IPAP may be increased with increment of 2 cm of H_2O to improve alveolar ventilation. Similarly, EPAP may also be increased to improve oxygenation. When EPAP and IPAP are equal, it behaves like CPAP.

Indications of Bi-PAP

Bi-PAP has value in preventing endotracheal intubation in many conditions leading to respiratory failure, such as COPD, pulmonary edema, pneumonia, acute lung injury and ARDS. It also helps in weaning and avoiding intubation in patients with respiratory failure during postextubation period.

NEWER MODES OF MECHANICAL VENTILATION

Inverse Ratio Ventilation (IRV)

IRV is not a different mode of ventilation, instead it is a maneuver to improve oxygenation in cases with severe hypoxic respiratory failure. During IRV, inspiratory time is kept equal/more than expiratory time resulting in I:E ratio is greater than 1. There are two general ways to apply IRV:

1. Pressure-Controlled IRV (PC-IRV), in which a preset airway pressure is delivered for a fixed period of time.
2. Volume-Controlled IRV (VC-IRV), in which a tidal volume is delivered at a slow (decelerating) inspiratory flow rate, keeping I:E ratio greater than 1.

For PC-IRV, variables controlled by the physician must specify the inspiratory airway pressure, f and I:E ratio, while VT and flow profile are determined by respiratory system impedance as discussed for PCV. The commonly used initial settings for PC-IRV are:

Pinsp = 20–40 cm H_2O (or 10–30 cmH_2O above the PEEP),
f = 20/min and the I:E = 2:1 to 4:1

For VC-IRV, the operator selects a tidal volume, f, V (a low value), flow profile and possibly, an end-inspiratory pause. The chosen values result in an I:E ratio greater than 1:1 and as high as 5:1. As there a risk of auto PEEP, the PC-IRV is preferred over VC-IRV.

Compared with conventional modes of ventilation, lung oxygen exchange is often improved on IRV. The mechanisms involved are increased mean alveolar pressure and volume, creation of auto PEEP, which reduces shunt by redistributing alveolar edema into the pulmonary interstitium.[34,35] Major disadvantage of IRC (both PC-IRV and VC-IRV) is requirement of heavy sedation with or without muscle paralysis, which may have adverse effect on the outcome.

High Frequency Ventilation

High Frequency Ventilation (HFV) attempts to achieve adequate gas exchange, by using asymmetrical velocity profiles when combining very high respiratory rates with V_T smaller than the volume of anatomic dead space (Fig. 140.6). These modes include High Frequency Oscillatory Ventilation (HFOV) and High Frequency Jet Ventilation (HFJV). It is used more commonly in neonates and infants with neonatal respiratory failure. There has been a renewed interest in using HFV in adult patients with ALI/ARDS, with the rationale that the small tidal volumes may cause less ventilator associated lung injury. Theoretical benefits of HFV include, lower risk of barotrauma due to smaller tidal excursions, improved gas exchange through a more uniform distribution of ventilation and improved healing of bronchopleural fistulas.[36] A substantial risk is that dynamic hyperinflation is the rule. However, more trials are necessary to determine, if HFV can improve mortality outcomes in these patients. [37]

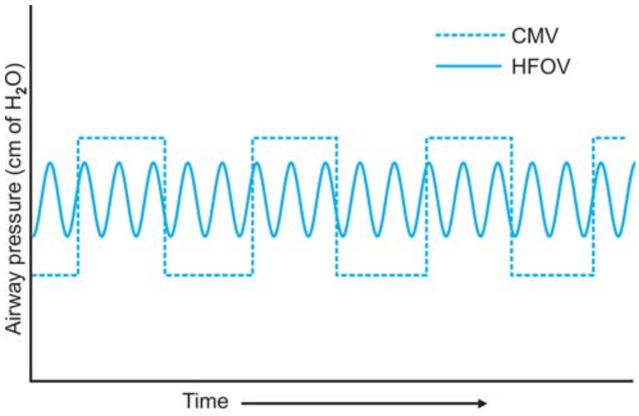

Fig. 140.6: A graphical presentation of high frequency ventilation (solid line), comparing the controlled ventilation (dotted line)

Airway Pressure Release Ventilation (APRV)

Airway pressure release ventilation is similar to CPAP, in that patient is allowed to breathe spontaneously without restriction. During APRV, the clinician sets a "pressure high", "pressure low" and a time at each level (time high and time low) (Fig. 140.7). Ventilation occurs during the release from pressure high to pressure low. The "time low" is typically 0.2–0.8 seconds in restrictive lung disease and 0.8–1.5 seconds in obstructive lung disease. It is probably most prudent to start at 0.8 and titrate to meet individual patient requirements. The time low is also referred to as the release phase.[38] During spontaneous exhalation, the PEEP is dropped (released) to lower level, this action simulates the process of exhalation. A common occurrence in this mode is setting the "time low" too long. This essentially mimics a pressure-targeted SIMV strategy. The patient typically spends 4–6 seconds in "time high".

In the paralyzed patient APRV/Bi-Level is identical to pressure targeted inverse ratio ventilation. For these reasons, some have described this mode as Inverse Ratio Ventilation (IRV). However, a major difference between APRV/Bi-Level and IRV is that IRV typically requires chemical paralysis or heavy sedation. APRV/Bi-Level allows for spontaneous breathing throughout both pressure levels, making it relatively more comfortable and typically does not require heavy sedation or paralysis. APRV/Bi-Level has gained popularity in patients with hypoxemic respiratory failure because it improves oxygenation by optimizing alveolar recruitment and V/Q matching.[39]

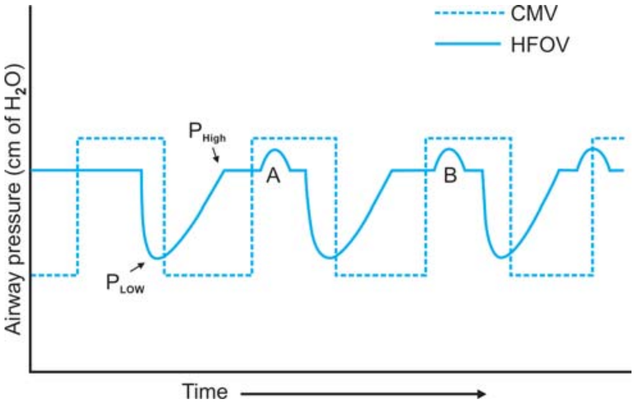

Fig. 140.7: A graphical presentation of airway pressure release ventilation (solid line), as compared to controlled ventilation (dotted line). This pressure-time tracing is showing two spontaneous breaths (a and b) at P_{High}

Proportional Assist Ventilation (PAV)

This is a form of partial ventilatory support developed to avoid some of the adverse effects of CMV, such excessive ventilation, use of sedative/paralytic agents and muscle disuse atrophy. Proportional Assist Ventilation (PAV) is based on the principle that during partial support, the Pressure applied to the Respiratory System (P_{RS}) is contributed by the Pressure produced by the Respiratory Muscles (P_{MUS}) and the Ventilator (P_{AW}), the latter of which represents the amount of assistance delivered.

$$P_{RS} = P_{MUS} + P_{AW}$$

The load imposed on the respiratory muscles during assisted ventilation can be described by the equation of motion as follows:

$$P_{MUS} = R \times \dot{V} + E \times VT + PEEPi - P_{AW}$$

where V is flow, VT indicates volume displacement, R is respiratory system resistance, E is respiratory system elastance, and PEEPi is the end-expiratory elastic recoil pressure, which the respiratory muscles must overcome at the onset of inspiration to trigger the ventilator. During PAV, the ventilator instantaneously delivers positive pressure throughout inspiration, in proportion to patient-generated flow (flow assist, units cm $H_2O/l/s$) and volume (volume assist, units cm H_2O/l). The pressure applied by the ventilator (P_{AW}) therefore is:

$$P_{AW} = FA \times \dot{V} + VA \times VT$$

During PAV, the ventilatory support depends on patient's efforts, the more the demand, the greater will be the delivered pressure, flow and volume.[40] It does not apply a set pressure, flow or volume, instead it boosts the sensed patient effort according to a proportion set by the clinician. This contrasts with volume assist ventilation, where flow and volume may be "pulled down" by the effort. PAV also contrasts with pressure assist/support, in which flow and volume are affected by the effort but pressure is not.

Advantages of PAV

PAV has been shown to be effective in unloading the respiratory muscles,[33,41-43] without imposing a fixed breathing pattern,[44] in enhancing patient comfort,[45] and patient-ventilator interaction.[46] Two recent, randomized clinical trials have demonstrated, improved patient comfort during noninvasive ventilation with PAV compared with PSV. [47,48]

Complications of PAV

Despite these positive results, PAV still seems to be more of an intellectually satisfying research tool than a ventilatory treatment in the clinical setting. There are number of practical limitations which hinder the use of PAV.[40] The most important limitation is that proper adjustments of PAV settings require knowledge of the mechanical characteristics of the respiratory system, this information is not easy to obtain in patients receiving partial support.[49-53] Furthermore, the PAV algorithm is based on the equation of motion, which assumes resistance and elastance to be linear within the tidal breathing range. This assumption may not always be valid in ICU patients. Moreover, neuromechanical coupling, the transformation of respiratory muscle activation into mechanical output (P_{MUS}) is important for tidal breaths. There are several factors which can lead to neuromechanical uncoupling in ICU setting, such as fatigue, electrolyte, acid-base disorders and shock contributing to decreased P_{MUS}.[54-57] Other problems which may be observed during PAV include, ventilator-patient asynchrony and the presence of air leaks. [48]

Proportional Assist Ventilation Plus and Proportional Pressure Support

Proportional Assist Ventilation Plus (PAV+) and Proportional Pressure Support (PPS) are forms of synchronized ventilatory assistance, where the ventilator generates pressure in proportion to the patient's effort, i.e. the greater the effort, the more the pressure the ventilator generates. Therefore, the clinician determines the level of resistive and elastic unloading, irrespective of volume or flow requirements.

Neurally Adjusted Ventilatory Assist (NAVA)

Neurally adjusted ventilatory assist was developed in an attempt to overcome the limitations of PAV, while maintaining all of its potential advantages. During this mode of ventilation, the electrical activity of the inspiratory muscles is used as an index of the inspiratory neural drive.[58] The neural drive is measured as crural Diaphragm Electrical Activity (EAdi), detected by means of esophageal bipolar electrodes, as it express global diaphragm activation.[59-63] Further, esophageal electrodes are not affected by the activity of postural and expiratory muscles (cross-talk) or by the subcutaneous tissues, which can be a problem with skin surface electrodes. The array of bipolar electrodes can be mounted on a nasogastric tube, which is introduced in almost all critically ill patients. The signal obtained by these electrodes is then transferred to the ventilator to regulate the ventilation support, which is therefore instantaneously applied in relation to EAdi. Thus, cycling and the intrabreath assist profile are determined directly by the EAdi, whereas the amount of assistance for a given EAdi depends on a user-controlled gain factor. As the ventilator is triggered directly by EAdi with NAVA, the synchrony between neural and mechanical inspiratory time is guaranteed both at the onset and at the end of inspiration, regardless of PEEPi, air leaks and respiratory mechanics.

Advantages of NAVA

In the absence of any significant disease of the respiratory centers, phrenic nerves and neuromuscular junctions and drugs suppressing the ventilatory drive, the ventilatory support provided corresponds to the ventilatory demand of the patient, irrespective of variations in muscle length or contractility. The use of neural control of mechanical ventilation has the capability to dramatically enhance the coordination between mechanical ventilation and respiratory muscle activity, thereby improving patient comfort.

Limitations of NAVA

Although NAVA may be considered as a major advance in the care of the critically ill, it is not currently available for clinical use and serves only as a research tool. It has been used primarily in healthy subjects for short-term studies, by only a few investigators. The effects of this mode on breathing pattern and gas exchange have yet to be evaluated and it remains to determine, whether NAVA can maintain adequate levels of support in different kinds of respiratory failure from admission to weaning.

Biologically Variable Ventilation

Biologically Variable Ventilation (BVV) is a new mode, which was designed to improve the management of ARDS. Controlled mechanical ventilation is often required for treatment of ARDS, however the loss of physiological variability of breathing pattern may contribute to deterioration in respiratory mechanics and gas exchange.[64] Biologically variable ventilation mimics spontaneous breath-to-breath variability, incorporating natural variable noise into volume-targeted controlled mechanical ventilation, which may overcome this limitation. The ventilator has a programme to modulate respiratory rate and VT, while maintaining a fixed minute ventilation based on a previously generated data file.[64]

It is important to recollect that recruitment is a continuous and progressive phenomenon that depends not only on PEEP, but also on the inflation volume.[65-68] The rationale behind BVV is based on the concept that the alveolar recruitment achieved by high volumes exceeds the derecruitment caused by small volumes, resulting in improvement in lung compliance and oxygenation without an increase in mean airway pressure.[69]

Advantages of BVV

Biologically variable ventilation has been compared with conventional controlled ventilation in a series of animal studies. BVV significantly improved oxygenation in healthy animals during general anesthesia.[70] It has been shown to be useful after re-expansion of a collapsed lung and in ARDS, with and without PEEP.[64, 71, 72] Boker et al., also compared the low tidal volume ARDS network protocol with BVV in a porcine model of ARDS and found a decreased concentration of proinflammatory cytokines in the tracheal aspirate, improved oxygenation and decreased shunt fraction.[73] BVV variability results in periodic deep inflations and the mere application of periodic sighs has also been shown to provide beneficial effects.[65,74] Comparing these two strategies, BVV is found to be more effective than periodic sighs of the same magnitude and frequency as the higher BVV tidal volumes.[71]

Limitations of BVV

Although there are impressive results with BVV use in animal studies, no human study has been conducted yet. There are dissimilarities between different animal species, therefore the effects observed in animals should be carefully extrapolated to humans. Indeed, others have failed to reproduce the benefits of BVV in a canine model of oleic acid-induced ARDS.[75] Further, its effects on conditions of different severity or diverse origins are also not clear.[69]

Hybrid or Mixed Modes

Some ventilators allow combinations of modes, most commonly SIMV plus PSV. There is little reason to use such a hybrid mode, although some physicians use the SIMV mode as a means to add sighs to PSV, an option not otherwise generally available. It is advantageous in that SIMV plus PSV guarantees some backup minute ventilation (which PSV does not). It is many times used for difficult to wean patients.

INITIATING MECHANICAL VENTILATION

Initial Ventilator Settings

Initial ventilator settings depend on the goals of ventilation, i.e. full respiratory muscle rest versus partial exercise, the patient's respiratory system mechanics and the needed minute ventilation. Each critically ill patients present unique challenges. Some common clinical scenarios are described below:

Patients with Normal Lung Mechanics and Gas Exchange[76]

These patients may require mechanical ventilation because of:

1. Loss of central drive to breathe (drug overdose or structural injury to the brainstem).
2. Due to neuromuscular weakness (high cervical myelopathy, myasthenia gravis).
3. Treatment of shock (as adjuvant therapy).
4. To achieve hyperventilation (treatment of raised intracranial pressure).

Following are the acceptable initial setting after intubation:

FiO_2 of 0.5 to 1.0
VT 8 to 12 ml/kg, f of 8 to 12 per minute
Inspiratory flow rate of 40 to 60 l/min

In patients with preserved respiratory derive and without profound weakness, PSV can be used. The pressure support is adjusted (usually 10 to 20 cm H_2O above PEEP), to bring the respiratory rate down into the low twenties, usually corresponding to tidal volumes of about 500 cc. It should be noted that PSV is entirely spontaneous, with no machine backup. Therefore, hypoventilation may occur despite the use of PSV, if there is further deterioration of muscle strength or blunting of respiratory drive. Once stabilized, effort should be made to bring down FiO_2 less than 0.6. For hyperventilation, the initial respiratory rate should be increased to the range of 16 to 20 breaths per minute. If patient complains of air hunger, the inspiratory flow rate can be increased, but 40 to 50 l/min is often sufficient,[24] flow greater than 60 l/min is rarely required.

Airway pressure and flow waveforms should be inspected for evidence of patient-ventilator dys-synchrony or undesired patient effort. To provide full rest, the patient's drive can be suppressed by increasing the inspiratory flow rate, frequency or tidal volume.[77] If such adjustments are ineffective, then sedation may be necessary. If sedatives also do not abolish inspiratory efforts and full rest is essential (as in shock), muscle paralysis should be considered.

Preventive measures for atelectasis should include sighs (6 to 12 per hour at 1.5 to 2 times the VT) or small amounts of PEEP (5 to 7.5 cm H_2O). This is specially required in patients with neuromuscular diseases. Three-point turning and chest physiotherapy are desirable in all patients, unless other conditions preclude their use. Rotating beds are effective in some patients in preventing atelectasis and pneumonia.[78]

Patients with Severe Airflow Obstruction

The common conditions included in this category are bronchial asthma and Chronic Obstructive Pulmonary Disease (COPD).

Bronchial asthma: Patients with acute severe asthma requiring mechanical ventilation are usually extremely anxious and distressed. Deep sedation should be routinely provided, a few patients may require therapeutic paralysis, although paralytic drugs occasionally causes long lasting weakness.[79,80] These interventions help to reduce oxygen consumption (and hence carbon dioxide production), to lower airway pressures and to reduce the risk of self-extubation.

The gas exchange abnormalities of airflow obstruction are largely due to ventilation-perfusion mismatch. Ventilation should be initiated using the A/C mode (or SIMV), the tidal volume should be small (5 to 7 ml/kg) and the respiratory rate should be 12 to 15 breaths per minute. A peak flow of 60 l/min is recommended, higher flow rates do not increase expiratory rate significantly. An FiO_2 of 0.5 suffices in the vast majority of patients.[81] Requirements for a higher FiO_2 should prompt a search for an alveolar filling problem or for lobar atelectasis. Finally, if the patient is triggering the ventilator, some PEEP should be added to reduce the work of triggering, although this may occasionally compound the dynamic hyperinflation, potentially compromising the cardiac output. Usually, auto-PEEP increases little as long as PEEP is not set higher than about 85% of the auto-PEEP.[82,83] The targets should be, to minimize alveolar overdistention (Pplat less than 30) and dynamic hyperinflation (auto-PEEP below 10 cm H_2O or end-inspiratory lung volume less than 20 ml/kg), a strategy that largely prevents barotrauma.[84] Reducing minute ventilation to achieve these goals generally causes the PCO_2 to rise above 40 mm Hg, (permissive hypercapnia) often to 70 mm Hg or higher. This requires sedation, such permissive hypercapnia is quite well tolerated.

Careful attention should be paid to the inspiratory flow and flow profile. The flow changes, which have little effect in normal individual without airflow obstruction, can have a dramatic impact in obstructed patients. Specifically, reduction in the inspiratory flow or switching to a decelerating flow profile, reduces the airway pressures and the amount of ventilator alarming. But the same actually worsens auto-PEEP, by prolonging inspiration. Therefore, a close watch should be kept on auto-PEEP and expiratory flow profile.

Chronic obstructive pulmonary disease: Unlike patients with status asthmaticus, COPD patients have expiratory flow limitation, arising largely from loss of elastic recoil. As a consequence, in a patient with COPD, the peak airway pressures on the ventilator tend not to be extraordinarily high, still auto-PEEP and its consequences are common.[85] The majority of patients with COPD will appear exhausted, at the time when mechanical support is instituted and will sleep with minimal sedation. To the extent that muscle fatigue has played a role in a patient's functional decline, rest and sleep are desirable. Also, such a patient has underlying compensated respiratory acidosis. Hyperventilation carries the risk of severe respiratory alkalosis and bicarbonate wasting by the kidney. The initial ventilator settings of a tidal volume of 5 to 7 ml/kg and a respiratory rate of 24 to 28 breaths per minute, with either an SIMV or an A/C mode, set on minimal sensitivity can achieve the goal of rest and relative hypoventilation. Usually, good oxygenation can be achieved with a FiO_2 of 0.4. Inspiratory flow rates may be adjusted for patient comfort, but usually in the range of 60 l/min. PEEP should be used, when the patient is triggering the ventilator, but is not required in sedated patient.

Usually, two to three days of rest restore biochemical and functional changes associated with muscle fatigue, but 24 hours is probably not sufficient.[54] A few patients on the ventilator are difficult to rest and continue to demonstrate a high work of breathing. Airway pressure and flow waveforms may be used to identify these patients and strategies for improving the ventilator settings. Auto-PEEP may be responsible for this problem, when addition of extrinsic PEEP to nearly counterbalance the auto-PEEP may dramatically improve the patient's comfort.[83] Another approach is to increase minute ventilation, although this worsens auto-PEEP and bicarbonate loss. A careful search should be made for problems that might drive the patient to a respiratory rate higher than is desirable, e.g. hypoperfusion, pleural effusion or pain. If the patient continues to make significant inspiratory efforts after correction, judicious sedation is advised. Once the patient improves and the respiratory muscles are adequately rested, the patient should assume some of the work of breathing and be evaluated for weaning. During this phase, some extrinsic PEEP is typically useful to reduce the work of triggering.[83]

Patients with Acute Lung Injury (ALI) or Adult Respiratory Distress Syndrome (ARDS)

Acute lung injury and ARDS are inflammatory conditions, resulting from a broad spectrum of lung injury leading to mild respiratory abnormality to severe respiratory derangement. Respiratory dysfunction often develops during early phase of (within 48 hours) of the physiologic insult,[86] may take weeks to months to resolve. Regardless of the cause, the pulmonary physiology and the mechanics are altered, leading to hypoxemic respiratory failure. The use of positive pressure ventilation itself may cause lung injury (Ventilation induced lung injury), that may amplify pre-existing injury, delay lung recovery and result in adverse outcomes. In ARDS, the Functional Residual Capacity (FRC) is reduced due to alveolar flooding and collapse, leaving fewer alveoli to accept the tidal volume. This result in stiff lung, the work of breathing is increased dramatically. The ARDS lung should be viewed as a small lung (baby lung), rather than a stiff lung. In line with this current conception of ARDS, ventilatory strategies have evolved markedly in the past decade. The goals of ventilation are to reduce shunt, avoid toxic concentrations of oxygen and choose ventilator settings that do not amplify lung damage.

The initial FiO_2 should be 1.0, in view of the typically extreme hypoxemia. PEEP should be instituted immediately, beginning with 15 cm H_2O, rapidly adjusted thereafter either to produce an arterial saturation of 90% on an FIO, less than 0.6 ("least PEEP approach") or a value 2 cm H_2O higher than the lower inflection point of the inflation pressure-volume curve ("open-lung approach").[87] The tidal volume should be 5 to 7 ml/kg on A/C or SIMV, since higher tidal volumes usually overdistend the lung at end inspiration, as judged by the upper inflection point of the respiratory pressure-volume curve,[88] which may even contribute to systemic inflammation.[89] Alternatively, PCV can be used with an inspiratory pressure (PEEP plus the pressure increment) of 30 to 35 cm H_2O. This will generally drive VT of 350 to 550 ml/kg. In both modes the respiratory rate of 24 to 28 breaths per minute is acceptable, as long as there is no auto-PEEP. The combination of high levels of PEEP (especially when the open-lung approach is used) and low end-inspiratory pressures, leaving only a small range for tidal ventilation is called as Lung Protective Ventilatory (LPV) strategy. A common consequence of LPV is hypercapnia ("permissive hypercapnia").

The ventilatory settings, which are followed most widely are based on ARDSnet trial.[90] The same protocol is summarized below:

A. *Target a tidal volume* of 6 ml/kg Predicted Body Weight (PBW), with a goal of plateau pressures of 30 cm H_2O or lower and adjust tidal volume according to ARDSNet guidelines. For patients who develop ALI, while receiving tidal volumes in excess of 6 ml/kg, stepwise reductions in tidal volume of 1 ml/kg every 15 minutes, with concomitant increases in respiratory rate to maintain constant minute ventilation is advised to ease the transition.
    1. Choose a mode of ventilation: Although any mode may be used, the sentinel ARDSNet trial results were based on the use of continuous mandatory ventilation (assist/control) mode with volume-controlled ventilation setting. Importantly, plateau pressure may not reflect transpulmonary pressure in pressure-limited modes (pressure-

controlled ventilation and pressure support ventilation). If the patient is making active inspiratory efforts that lower the pleural pressure, in this situation, delivered tidal volumes and transpulmonary pressures may approximate those in the control arm (12 ml/kg) of the ARDSNet trial.

2. Calculate PBW:
   - Males: PBW(kg) = 50 + 2.3 [height(inches) 60]
   - Females: PBW(kg) = 45.5 + 2.3 [height (inches) 60]
3. Choose tidal volume goal of 6 ml/kg PBW
4. Set PEEP to 5 cm H_2O or higher
5. Measure and record plateau pressure, atleast every 4 hours and after any changes in tidal volume and PEEP:
   a. If plateau pressure greater than 30 cm H_2O, reduce tidal volume to 5 ml/kg and then to 4 ml/kg PBW, if necessary and to decrease plateau pressure to 30 cm H_2O or lower.
   b. If tidal volume less than 6 ml/kg PBW and plateau pressure less than 25 cm H_2O, increase tidal volume by 1 ml/kg PBW to a maximum of 6 ml/kg.
6. Adjust respiratory rate or tidal volume according to pH goals:
   a. If pH less than 7.30, consider increasing the respiratory rate to as high as 35/min, while monitoring for development of auto-PEEP.
   b. If pH less than 7.15 and respiratory rate greater than 35/min, consider increasing tidal volume and suspending the plateau pressure limit, depending on patient tolerance of the acidemia.
7. If severe dyspnea (less than three double-triggered breaths per minute or if airway pressure remains at or below PEEP level during inspiration), increase tidal volume to 7 or 8 ml/kg PBW, if plateau pressure remains less than 30 cm H_2O. If plateau pressure greater than 30 cm H_2O on 7 or 8 ml/kg PBW, revert to lower tidal volume, consider ventilator adjustments to improve patient synchrony and consider more sedation.
8. Set PEEP or FiO_2, to achieve oxygenation target of PaO_2 55 to 80 mm Hg or SpO_2 of 88% to 95%, using the PEEP and FiO_2 combinations.
   a. Increase FiO_2 or PEEP within 5 minutes of consistent measurements below the oxygenation target range.
   b. Reduce FiO_2 or PEEP within 30 minutes of consistent measurements above the oxygenation target range.
   c. Assess lung recruitability for patients with PaO_2/FiO_2 lower than 150 (with PEEP = 5 cm H_2O), consider using the higher PEEP/lower FiO_2 to set PEEP and FiO_2, if either or both of the following occur when PEEP is increased:
      i. Increase in respiratory system compliance (when PEEP is increased from 5 to 15 cm H_2O).
      ii. Reduced dead space fraction (or decrease in $PaCO_2$ at constant minute ventilation and tidal volume), when PEEP is increased from 5 to 15 cm H_2O.

B. *Select PEEP and FiO_2,* according to oxygenation criteria, using PEEP-FiO_2 combinations within the two ranges tested in the alveoli trial. In patients with high FiO_2 requirements (PaO_2/FiO_2 less than 150 with PEEP 5 cm H_2O), who demonstrate a reduction dead space fraction (or a fall in $PaCO_2$ at constant minute ventilation and tidal volume) or an improvement in respiratory system compliance, when PEEP is increased from 5 to 15 cm H_2O, the authors advise use of the higher PEEP/lower FiO_2 table. For patients who experience a fall in respiratory compliance or a rise in dead space fraction, when PEEP is increased to 15 cm H_2O (indicating overdistension) or who have active barotrauma or adverse PEEP-induced cardiovascular changes, the authors advise use of the lower PEEP/higher FiO_2 table. The two approaches produce similar clinical outcomes, when applied to patients who have ALI/ARDS, regardless of lung recruitability. This stratification aims at targeting higher PEEP, to the recruitable subset of patients, although such an approach is logical, it remains to be shown, whether such an approach improves outcomes.

C. *Minimize contributors to patient-ventilator dys-synchrony* (e.g. adequate sedation, trigger sensitivity, flow and other factors).

COMPLICATIONS OF MECHANICAL VENTILATION

Mechanical ventilation is associated with multiple complications as demonstrated in Table 140.1. Some of them may be related temporally and not caused by ventilatory support per sec, but many are a direct result of positive-pressure ventilation.

TABLE 140.1: Common complications associated with MV

Endotracheal intubation	*Complications*
a. During intubation	Trauma to teeth and soft tissue
	Esophageal intubation
	Vomiting and aspiration
	Hypoxia
	Arrhythmia
	Bradycardia
b. While intubated	Obstruction
	Pneumonia and atelectasis
	Aspiration
	Kinking of ET tube
	Mucosal injury
	Improper position
	Accidental extubation
c. Post extubation	Aspiration
	Laryngospasm
	Hoarness
	Laryngeal or subglottic edema
	Laryngeal stenosis
	Tracheal stenosis
Positive pressure ventilation	
a. Pulmonary	Barotrauma
	Ventilator associated pneumonia
	Deconditioning of respiratory muscles
	Oxygen toxicity
b. Extrapulmonary	Raised intracranial tension
	Hypotension
	Stress ulcer and cholestasis
	Renal dysfunction

A successful outcome of mechanical ventilation depends upon the avoidance and presentation of complications. Comprehensive intensive care of patient can therefore, be considered as essential component of mechanical ventilation.

Noninvasive Ventilation

GC Khilnani, Vijay Hadda

INTRODUCTION

Assisted ventilation is an integral part of critical care which has significantly improved the outcome of these patients. However, conventional mechanical ventilation is associated with several complications, a large proportions of these are related to endotracheal intubation. Noninvasive Ventilation (NIV) refers to technique of augmenting alveolar ventilation without an endotracheal airway, thereby avoiding many of these complications. Since its first use in 1980s in patient with neuromuscular respiratory failure, NIV is considered as one of the most important addition in the field of mechanical ventilation and critical care armamentarium. Over the last two decades, it has gained widespread acceptance as a mode of assisted ventilation for the management of acute, as well as chronic respiratory failure in different settings including in emergency departments, Intensive Care Units (ICUs), wards and at home.[1-7]

Technically, NIV refers to the provision of inspiratory pressure support plus Positive End-Expiratory Pressure (PEEP) via a nasal or face mask. Although continuous Positive Airway Pressure (CPAP) does not actively assist inspiration and is not a ventilatory support mode, it is considered a form of NIV, when used as a therapy for respiratory failure. The use of NIV therapy in selected patients with acute respiratory failure is associated with significantly reduced need for endotracheal intubation and conventional ventilation. The available evidence suggests that the benefits of this therapy are not limited to hypercapnic acute respiratory failure but extend to hypoxemic acute respiratory failure as well. The successful application of NIV requires the training and collaboration of an experienced ICU team, including intensivists, nurses and respiratory physiotherapists.[1, 8] Proper selection of the patient based on various clinical and laboratory parameters cannot be ignored as an important factor deciding the success of this therapy. An expanded awareness of NIV devices and techniques promises to increase the therapeutic options for patients with severe respiratory insufficiency. This chapter summarizes the technique and mechanism of action of NIV, along with its efficacy in acute and chronic form of respiratory failure, clinical uses and limitations.

TECHNICAL ASPECT OF NONINVASIVE VENTILATION

Types of Noninvasive Ventilation

Noninvasive mechanical ventilation support can be either negative pressure ventilation or positive pressure ventilation.

Negative Pressure Ventilation

The negative pressure ventilators were widely used during polio epidemics, the classical example was the ‘iron lung’. The principle of negative pressure ventilation involves the application of external sub-atmospheric pressure to the chest wall, resulting in its expansion during inspiration, expiration occurs as the pressure around the chest wall is allowed to return to atmospheric level.[9] During negative pressure ventilation, tidal volume is related to peak inspiratory negative pressure (more the negative pressure, more the tidal volume) and the pressure waveform (a square wave produces a greater tidal volume than a half sine wave) generated by the ventilator pump. This type of ventilation has been used in patients with respiratory failure due to chest wall deformity, neuromuscular diseases or central hypoventilation.[9-11] Recently, negative pressure ventilation has been shown to be associated with a higher PaO_2, a lower $PaCO_2$ (despite identical minute ventilation), and less lung injury in an animal study.[12] It may motivate the researchers for similar trials in human subjects. However, the use of negative pressure ventilation is limited by their propensity of causing upper airway obstruction leading to oxygen desaturation and poor acceptance by patients due to the awkward size of devices.[10] The positive pressure ventilation administered by nasal mask, overcame some of these shortcomings, especially ameliorating the nocturnal oxygen desaturation.[13]

Noninvasive Positive Pressure Ventilation (NIPPV)

For several decades, positive pressure ventilation has been delivered by endotracheal intubation as standard of care to patients with various forms of respiratory failure. Noninvasive Positive Pressure Ventilation (NIPPV) refers to the positive pressure ventilation provided without the use of endotracheal intubation. The technique requires a mechanical ventilator, connected by tubing to an interface (nasal, orofacial and other types of mask). The ventilator delivers continuous or intermittent positive airway pressure through the upper airway and actively assists the ventilation. NIPPV is used in selected patients with various forms of respiratory failure.[1,14-17]

The Equipment of NIPPV

Ventilator Device

The primary requirement for NIPPV is a device to deliver positive pressure ventilation (ventilator) and an appropriate patient-ventilator interface (orofacial or nasal mask). The choice of ventilators available to provide noninvasive ventilatory support has continued to expand. Noninvasive ventilatory support may be provided either by using large bedside critical care volume ventilators or a specialty ventilator devoted to noninvasive ventilation. A dedicated NIPPV ventilator is a small, compact, portable machine connected to the interface (nasal, orofacial or other types of mask) via tubing (Fig. 141.1). Many critical care ventilators currently in use also have a NIPPV option, either as part of the original device or available as an upgrade option. While the critical care ventilators have more options of several modes and better oxygen blending, they are also less tolerant of leaks. The specialty ventilators have fewer options and range, but are more leak-tolerant. The ideal device is dependent on a number of factors, including the familiarity of the staff and the availability of options. The differences between the bedside critical care ventilator and specialty noninvasive ventilator continue to diminish as the differences related to ventilator options, range of support and leak tolerance are corrected in both devices. The size is an important consideration. Therefore, specialty ventilators which are small in size (Fig. 141.1) are used both in hospitals and in home.

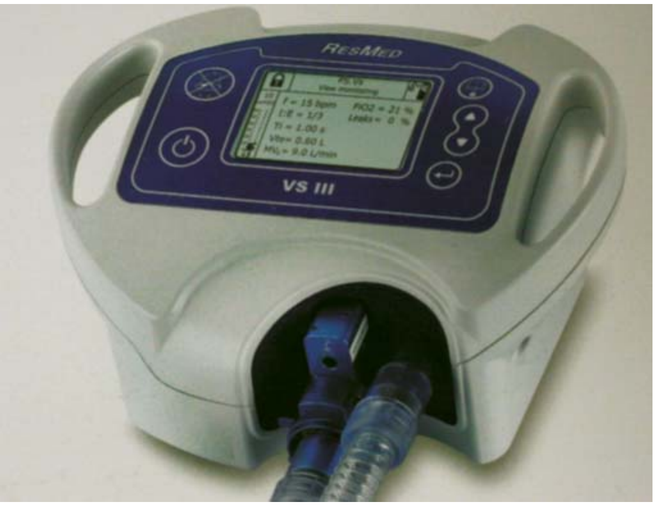

Fig. 141.1: Noninvasive mechanical ventilation machine

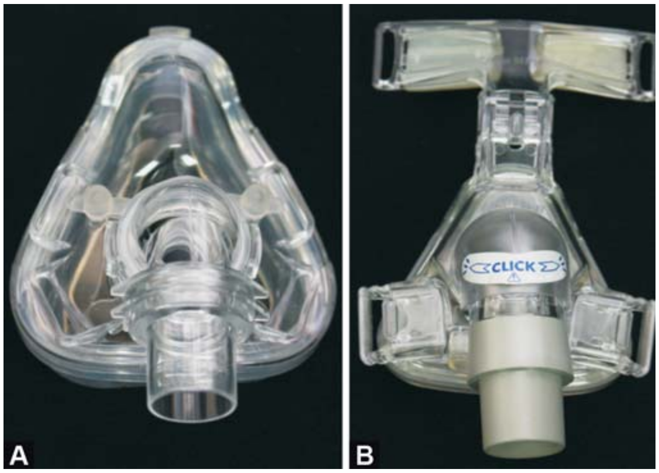
Interfaces

The interface between the machine and the patient is a tight fitting mask that is made of silicon (Figs 141.2A and B). Nasal masks and orofacial masks were the earliest interfaces, with subsequent development and use of full face masks, mouthpieces, nasal pillows, and helmets.[8] This advancement gives liberty to the care provider to select interface as per indication and tolerance of the patient. Nasal masks and orofacial masks are still the most commonly used interfaces. Both nasal and a full-face mask are held in place by cloth straps or Velcro (Fig. 141.3). These masks are available in various sizes. The choice of mask depends upon the comfort and compliance of the patient, as well as on the operator choice.

Orofacial masks are the most frequently used interface for management of acute respiratory failure.



Figs 141.2A and B: Commonly used interfaces, (A) orofacial and (B) nasal masks

Fig. 141.3: Typical headgear used to hold the interface

Use of these masks compared to nasal masks lead to faster correction of blood gases. Orofacial masks are preferred in patients who are less cooperative, have a higher severity of illness, are mouth-breathers or pursed-lips breathers, edentulous and those requiring more effective ventilation. However, these masks are associated with claustrophobia, hindrance in speaking and coughing and carry a small risk of aspiration with emesis. Nasal masks are best suited for more cooperative patients with a lesser severity of illness. These are not claustrophobic, allow speaking, drinking, coughing, secretion clearance, carry lesser risk of aspiration and emesis. However, these are associated with more air leaks (e.g. mouth-breathing or edentulous patients) and effectiveness is limited in patients with nasal deformities or blockade.

Importantly, mask should be the proper sized, so that it snugly fits and there is no air leak. Indeed, selection of appropriate mask and its proper application is of paramount importance for success of this form of ventilation, air leak leads to ineffective ventilation. Leaks are the bane of all of the interfaces, but excess pressure applied with the straps is discomforting to the patients, increases the risk of pressure necrosis and skin breakdown. Some amount of air leak at times is inevitable; however, most of the machines have facility for leak compensation. Therefore, one should be careful to minimize excess pressure on the face or nose. Straps should be tight enough to prevent significant leaks, but with enough slack to allow passage of 1 or 2 fingers between the face and the straps.[1,8]

Various Modes of Ventilation

NIPPV usually provides a form of assisted ventilation, where every breath is supported by the ventilator. Two types of breaths can be used, either volume targeted or pressure targeted.

Volume Targeted NIPPV

During volume targeted breaths, a predetermined tidal volume is delivered, usually with a set peak-flow rate and a controlled flow wave shape, over a fixed inspiratory time. It is frequently recommended to set tidal volume higher than usual, to compensate for possible leaks (12–14 ml/kg). In "invasively" ventilated patients, much attention has been paid to the importance of the peak-flow setting in relieving the patient's dyspnoea and reducing effort.[18,19] Surprisingly, little attention is paid to the importance of this peak-flow setting, while providing volume controlled ventilation with NIPPV. The usual peak-flow rate of 45–60 l/min is essential to decrease patient's inspiratory effort. Excessive peak-flow rates, however, also have adverse effects, as they can increase the sense of dyspnoea (the patient receives "too much air").[18,20] Unfortunately, some of the "old" generation ventilators cannot be used for volume targeted NIPPV. Modern ventilators have been designed to deliver volume targeted NIPPV; however, in the case of leaks, the delivered volume is reduced, with no adaptation by the ventilator.

Pressure Targeted NIPPV

In case of pressure targeted NIPPV, the ventilator maintains a constant preset pressure after the breath has been triggered by the patient and stops when the flow decreases to a given threshold (similar to PSV) which is supposed to indicate the end of the patient's effort or after a fixed, preset inspiratory time (assist pressure control). The potential advantages of a pressure targeted NIPPV include: 1) in case of leaks, the preset pressure is maintained, which facilitates achieving an appropriate delivered volume; 2) because the pressure is limited in the mask, the likelihood of leaks and its side effects is reduced; 3) synchrony between the patient and the ventilator is usually good, since these modes have been primarily designed to facilitate the patient's effort to breathe; 4) the combination of PSV and PEEP has been shown to be very efficient in reducing the work of breathing.[21,22]

Choosing the initial mode of ventilation is based in part on the underlying disease, the ventilator available and the past experience. Pressure targeted ventilation with Continuous Positive Airway Pressure (CPAP) is the most basic level of support and is not considered as a mode of NIPPV in true sense. CPAP is most frequently used for management of cardiogenic pulmonary edema and obstructive sleep apnea.

Most patients on NIPPV require pressure support mode of ventilation with PEEP (popularly called BiPAP). During BiPAP mode, patient receives ventilatory support during both phases of respiration, as preset Inspiratory Positive Airway Pressure (IPAP) and Expiratory Positive Airway Pressure (EPAP). The difference between IPAP and EPAP is a reflection of the amount of pressure support ventilation provided to the patient and EPAP is synonymous with PEEP. Some non-invasive ventilators have facilities of proportional-assist ventilation (PAV), which provides flow and volume assistance with each breath.

While volume ventilators can be used to provide non-invasive ventilatory support, the pressure targeted modes are preferred because they provide better patient comfort and synchrony and are more tolerant of the leaks that accompany all noninvasive ventilatory interfaces.

Mechanism of Action of NIPPV

Intermittent positive pressure is transmitted through upper airway to the alveoli, increasing transpulmonary pressure, inflating the lungs and assisting alveolar ventilation, as in the case with positive pressure ventilation through an artificial airway. It has been stated that NIPPV improves day time ventilatory muscle function by reducing chronic respiratory muscle fatigue, improving respiratory system compliance through reversal of microatelectasis of lung and preventing nocturnal hypoventilation by resetting the respiratory center's sensitivity to carbon dioxide.

STEPS TO SUCESSFUL PROVISION OF NIPPV

Several considerations can enhance the likelihood of successful noninvasive positive pressure ventilation (NIPPV), such as proper selection of patient, settings (ICU/ward/home), the type of interface used, underlying disease, and patient's co-operation. In addition to these factors, the experience and expertise of health care providers including the nurses and the respiratory physiotherapist, is important for the success of NIPPV.

Choosing the Patients

It is most essential to choose the right patient for initiating NIPPV. A poor selection of patient leads to higher rate of failure of NIPPV. It is important to ensure that patient is able to understand the instructions. Although altered level of consciousness is a relative contraindication, patients with Chronic Obstructive Pulmonary Disease (COPD) with impaired consciousness may be given a trial of NIPPV for 30 to 60 minutes; quite often, there is improvement in the level of consciousness. Other contraindications to its use include hemodynamic instability, presence of copious respiratory secretions, impaired swallowing reflex, active upper gastrointestinal bleeding, and orofacial trauma. Hemodynamic parameters are important considerations; presence of hemodynamic instability or associated organ failure in a patient with respiratory failure carries a risk of failure of NIPPV. History of recent facial surgery, trauma or deformity are obvious contraindications. Patients should be carefully assessed for contraindications before the decision to initiate NIPPV is taken (Table 141.1).

Location of NIPPV Application

Initially, it was recommended that NIPPV should be initiated only in the ICU since some proportion of

TABLE 141.1: Contraindications to use of NIPPV

a. Uncooperative/obtunded patient
b. Agitated patient
c. Hemodynamic instability or presence of organ failure
d. Severe co-morbidity
e. Recent facial/upper airway trauma
f. Recent upper gastrointestinal tract surgery
g. Intestinal obstruction
h. Excessive secretions in the airways
i. Undrained pneumothorax

patients would require endotracheal intubation. It has now been recognized that this modality can be used in general wards.[5] Many other trials have demonstrated its therapeutic use outside ICUs in the emergency room, general wards and high dependency units (HDUs) subject to the availability of trained and experienced nursing staff and respiratory therapists.[3,4,6,7] The location of NIPPV therapy is largely determined by the severity of the illness. For example, patients with acute respiratory failure due to exacerbation of COPD with pH less than 7.25 are best managed in ICU.

Explanation and Evaluation

Physician should explain to the patient about the breathing support being provided to him and its benefits. Patients should also be provided a feel of the interface. It can be done by holding the mask with hands, without applying straps. It is useful to inform the patient that some discomfort might occur in the beginning due to tight fitting mask and the repeated gush of air with each inspiration. This helps the patient in understanding the working of the device which leads to reduction in the anxiety and better cooperation.

Initial Ventilator Settings and Adjustments

The primary goals of NIPPV are adequate ventilation and oxygenation, correction of respiratory failure, and adequate patient tolerance and comfort.[23] The ventilatory settings and adjustments are made to achieve these endpoints. Initial settings focus on achieving adequate tidal volumes, usually in the range of 5–7 ml/kg. Additional support is provided to reduce the respiratory rate to less than 25 breaths/minute. Oxygen is adjusted to achieve adequate oxygenation, so as to achieve hemoglobin oxygen saturation of more than 90%. Serial arterial blood gas measurements are essential to monitor the response to therapy and to guide further adjustments in the ventilator settings.

All patients should be initiated on a pressure support that is lower than the target level. To start with, an IPAP of 6 cm of water with EPAP of 2 cm of water is a reasonable setting. A pressure difference of 4 cm of water between IPAP and EPAP is desirable. Pressure may be augmented every few minutes by 2 cm of water, to reach a target level to achieve the therapeutic end points. The maximum recommended level of IPAP is 24 cm of water, whereas that of EPAP is 16 cm of water. Oxygen should be supplemented through a port provided in the mask or in the NIPPV machine at a flow rate, so as to maintain oxygen saturation above 90%.

TABLE 141.2: Indications of discontinuation of NIPPV

Major criteria (any 1 of the following)	*Minor criteria (2 of the following)*
• Respiratory arrest • Loss of consciousness • Gasping for air • Psychomotor agitation requiring sedation • Heart rate less than 50/minute with loss of alertness • Hemodynamic instability	• Respiratory rate greater than 35 breaths/minute • pH < 7.30 and decreased from onset • PaO_2 < 45 mm Hg despite oxygen • Increase in encephalopathy and decreased level of consciousness

Monitoring of Patients on NIPPV

Patient should be monitored for patient-ventilator asynchrony, deterioration of sensorium, gastric distention and development of air leaks as patient changes posture or speaks. Pulse rate, blood pressure, respiratory rate, signs of respiratory distress and oxygen saturation should be monitored during the first hour. Arterial blood gases (ABG) must be repeated within the first hour and monitored as and when necessary. A rising $PaCO_2$ with fall in pH should be taken as a sign of failure of NIPPV, invasive ventilation should be considered. Table 141.2 enumerates clinical situations where discontinuation of NIPPV should be considered. It must be remembered that a delay in decision regarding initiation of invasive ventilation is far worse than not considering NIPPV at all.

Predictors of Response to NIPPV

It is important to recognize that certain parameters may predict success or failure of NIPPV, so that patients are not subjected to unduly prolonged treatment with NIPPV, while optimal treatment requires endotracheal intubation and conventional mechanical ventilation. These parameters should be observed during a trial of noninvasive ventilation (Table 141.3). These parameters, in turn, are a reflection of the patient's ability to cooperate with noninvasive ventilation, patient-ventilatory synchrony and efficacy of noninvasive ventilation for the clinical situation. Trials of NIPPV are usually of 1 to 2 hour duration and are useful to determine if a patient can be managed by this modality. Extended trials without significant improvement are not recommended, this only delays intubation and mechanical ventilation (unless patients are "do-not-intubate" status). Trials may be as short as of a few minutes in patients with immediate

TABLE 141.3: Predictors of response to NIPPV

Predictors of success response to trial of NIPPV (1–2 hours)

- Improvement in $PaCO_2$ (a decrease of greater than 8 mm Hg)
- Improvement in pH (greater than 0.06)
- Correction of respiratory acidosis

Predictors of failure

- Severity of illness
  - Acidosis (pH <7.25)
  - Hypercapnia (>80 and pH <7.25)
  - Acute Physiology and Chronic Health Evaluation II (APACHE II) score higher than 20
- Level of consciousness
  - Neurologic score (>4 = stuporous, arousal only after vigorous stimulation; inconsistently follows commands)
  - Encephalopathy score (>3 = major confusion, daytime sleepiness or agitation)
  - Glasgow Coma Scale score lower than 8
- Failure of improvement with 12–24 hours of noninvasive ventilation

Late failures (>48 hours after initiation of NIPPV)

- Admission predictors of failure
  - Lower functional status (Activity score < 2 = dyspnea on light activity)
  - Initial acidosis (pH ≤7.22)
  - Hospital complications (pneumonia, shock, coma)

failure and probably should not exceed 2 hours if patients fail to improve.

Objective criteria for discontinuation are important to limit trials in patients in whom noninvasive ventilation ultimately fails (Table 141.2). The patients who are fulfilling these criteria are best managed by invasive mechanical ventilation, hence also referred as intubation criteria. These criteria, although carry a subjective element, have been defined in investigational studies. All these criteria are subject to some degree of interpretation in the context of the patient's clinical status. However, most patients who meet these criteria are candidates for intubation.

CLINICAL USES OF NIPPV: EVIDENCE AND RECOMMENDATIONS

Hypercapnic Respiratory Failure

Chronic Obstructive Pulmonary Disease

After several randomized controlled trials, a general consensus has been reached that NIPPV has an important role in the management of selected patients with acute respiratory failure due to exacerbation of COPD.[8,14,24] This therapeutic modality has also been used in chronic stable phase of COPD and for facilitation of extubation in patients who required intubation.[24]

NIPPV in Acute Exacerbation of COPD: Use of NIPPV for management of acute respiratory failure (ARF) secondary to acute exacerbation of COPD is now the standard of care. NIPPV acts primarily by reducing patient's effort and work of breathing in patients with COPD presenting with acute exacerbation.[25] Several randomized trials have documented reduction in requirement of endotracheal intubation, ICU and hospital stay, and mortality.[2,26,27] Brochard was the first to document these benefits in a prospective- randomized trial including 85 patients with ARF, due to acute exacerbation of COPD.[28] Subsequently, there have been several randomized trials which have documented benefit of this modality in patients with ARF secondary to COPD.[29] NIPPV also leads to reduced rate of nosocomial pneumonia and other complications related to endotracheal intubation. Therefore, all the patients with ARF secondary to COPD should receive benefit of NIPPV, unless there are contraindications. Patients with type II respiratory failure secondary to COPD with altered level of consciousness improve within 30 to 60 minutes with NIPPV. Therefore, such patients should get the therapy under close monitoring.

NIPPV in Chronic Stable COPD: The possibility that NIPPV might aid patient with severe chronic COPD has intrigued clinicians for decades. Earlier investigators thought that the intermittent use of NIPPV might give rest to the mechanically disadvantaged respiratory muscles, relieving chronic fatigue and enhance ventilatory and overall functions. Vitacca et al. demonstrated that in COPD patients with chronic hypercapnia, NIPPV led to improvement in arterial blood gases and unloading of respiratory muscles when pressures were set according to patients comfort and improvement in arterial blood gases.[30] Use of nocturnal NIPPV in chronic stable COPD patients with CO_2 retention leads to significant improvement in day time blood gases and sleep quality, compared to those receiving oxygen therapy alone.[31,32] The principal mechanisms for improved gas-exchange in patients with COPD following NIPPV include decreased gas trapping and increased ventilatory sensitivity to $PaCO_2$.[33] Changes in some volitional muscle strength measures may reflect improved patient effort.[33]

NIPPV significantly reduces ICU admissions, improves alveolar ventilation, exercise capacity, and quality of life.[34,35] However, not all the studies have shown benefit of NIPPV in chronic COPD. Some investigators have failed to show additional benefits from NIPPV over oxygen therapy and comprehensive rehabilitation programs.[36] The studies of Shapiro and Strumph discouraged the long-term use of NIPPV in severe stable COPD patients without significant hypercapnia.[36,37] Nocturnal NIPPV provides significant physiological and clinical benefits to stable patients with severe COPD with significant hypercapnia. NIPPV may be more effective in selected patients with hypercapnia and hypoxemia.[8,24]

Clearly, the data on mortality benefit of NIPPV use in long-term management of severe COPD is not robust enough to justify the routine use of NIPPV for home ventilation. However, given the positive impact of nocturnal use of NIPPV on physiological parameters, as well as subjective symptoms, there is significant benefit in terms of reduction of morbidity and possibly mortality. In fact, a selected group of patients may well benefit from domiciliary mechanical ventilation, we need to identify who they are. Moreover, NIPPV can be a new strategy to improve exercise tolerance in COPD patients. Larger studies designed to determine the impact of NIPPV on long term mortality in these patients are required and a routine use of NIPPV must await such data.[8,38]

Facilitating Extubation in COPD

Based on success of NIPPV in managing patients with ARF, there have been efforts to try the same in patients on conventional mechanical ventilation, in order to facilitate weaning and prevent reintubation in patients with COPD. In these patients, NIPPV can be used in three ways: 1) using NIPPV after early extubation, in order to reduce duration of invasive mechanical ventilation; 2) using it as a prophylactic measure to avoid respiratory failure and reintubation and 3) using as a therapeutic option in patients who develop respiratory distress after extubation, in order to avert endotracheal intubation.

The evidence suggest that NIPPV weaning was significantly associated with reduced mortality, fewer ventilator associated pneumonia, lesser length of ICU stay, hospitalization, total duration of ventilation and of duration of invasive ventilation.[39,40] Benefits in mortality and weaning failures were nonsignificantly greater in trials that exclusively enrolled patients with chronic obstructive pulmonary disease versus mixed populations.[41] Based on these findings, patients intubated for hypercapnic respiratory failure due to COPD who fail spontaneous breathing trials, should be considered for a trial of extubation to NIPPV. This approach should be reserved for patients who are good candidates for NIPPV in other respects and who are able to tolerate levels of pressure support easily administered via mask (i.e. 15 cm H_2O). In addition, there should not have been a difficult intubation.

Bronchial Asthma

Asthma exacerbations are similar to COPD exacerbations, there is increased airway obstruction, dynamic hyperinflation and impaired ventilatory effort, leading to respiratory muscle fatigue. However, there is a paucity of randomized controlled trials on the use of NIPPV in asthma. Still, positive results have been reported in a limited number of case reports, case series or uncontrolled studies with both CPAP and BiPAP.[42-47] NIPPV in asthma patients with acute respiratory failure has been associated with improved gas exchange and avoidance of intubation in an uncontrolled study.[44] A subsequent randomized pilot study in 33 patients with acute asthma but not acute respiratory failure, showed improved flow rates and decreased hospitalizations with NIPPV, compared to sham NIPPV.[48]

A trial of NIPPV before intubation and mechanical ventilation should be considered in selected patients with acute asthma and respiratory failure (evidence category B). These would include patients who can tolerate and cooperate with this therapy. NIPPV should only be used under close observation of the experienced respiratory therapists, nurses and physicians and in an area with facility of immediate intubation, if needed.[49]

Hypoxemic Respiratory Failure

Cardiogenic Pulmonary Edema

NIPPV has been used in patients with cardiogenic pulmonary edema for quite a long time; both CPAP and BiPAP have been used for the same. The favorable effects on lung mechanics include improvements in alveolar recruitment and functional residual capacity and reduction in anatomic shunting. It also reduces the work of breathing by decreasing the preload and after load. There is suggestion that the patients with cardiogenic pulmonary edema secondary to acute myocardial infarction get maximum benefits from this therapy.[50] There is always a concern of recurrence of myocardial infarction in these patients, there is enough evidence that this does not add to the risk of myocardial infarction and should not be considered as a contraindication to this therapy.[51] It may be avoided in patients who require emergency life saving procedure, such as percutaneous coronary intervention. NIPPV use has been shown to be associated with reductions in intubation and mortality rates.[52,53] Recently a large trial has challenged these findings in which no mortality benefit of NIPPV was observed in patients with acute cardiogenic pulmonary edema, although it showed a more rapid improvement in respiratory distress and metabolic disturbances than the standard oxygen therapy.[51] Thus, NIPPV should be used to treat acute cardiogenic pulmonary edema with expectations of success in terms of rapid improvement in symptoms and metabolic disturbances and probably reduced mortality and intubation rate (level A).[17]

Pneumonia

NIPPV has been used in patients with pneumonia and ARF with variable results.[54,55] The benefits of NIPPV include reduced intubation rates, ICU length of stay and mortality rate.[54,55] Among these, the patients with underlying COPD respond better than without the same. However, there is no strong evidence to support the routine use of NIPPV in patients with ARF due to pneumonia.

Acute Lung Injury/Acute Respiratory Distress Syndrome (ALI/ARDS)

Patients with acute lung injury/acute respiratory distress syndrome (ALI/ARDS) require conventional mechanical ventilation using various strategies. NIPPV has been tried in patients with ALI/ARDS in an effort to avoid endotracheal intubation.[56-58] Benefits of this modality are not well documented in these trials. Therefore, NIPPV should be used in these patients with caution, endotracheal intubation should not be delayed.

Respiratory Failure in Immunocompromised Patients

Immunocompromised patients who require endotracheal intubation have higher rate of ventilator associated pneumonia. The use of NIPPV in such patients leads to reduced rate of nosocomial infection which results in reduced mortality and ICU stay.[59,60] Therefore, the current recommendations strongly favor (level A) the use of NIPPV in immune-compromised patients with acute respiratory failure.[17,61]

Postoperative Respiratory Failure

NIPPV is widely used during postoperative period in patients with abdominal and thoracic surgery[62-67] It is believed that it provide better patient comfort and oxygenation after extubation. The current evidence shows only some usefulness of this modality, it does not strongly support the routine use of CPAP or NIPPV in postoperative patients, either prophylactically in high risk patients or as an early therapy of respiratory insufficiency. Although, data is sparse to support NIPPV, it can be safely used for respiratory distress in these patients.

Weaning or Postextubation Respiratory Failure

NIPPV during weaning or postextubation period has been used in three ways: (1) a *facilitation technique* for early extubation in patients who fail to meet standard extubation criteria;[39, 40, 68, 69] (2) a *rescue or curative technique* for avoiding reintubation in patients who fail extubation[70-72] and (3) a *preventive or prophylactic technique* for preventing extubation failure.[73-75] NIPPV has been suggested as a means to avoid reintubation and improve outcomes in patients with failed weaning. The first report to assess the role of NIPPV for weaning dates back to 1992, when it was successfully used in assisting the return of spontaneous breathing in a small group of patients with chronic respiratory insufficiency and weaning difficulties.[76] There have been conflicting results from various trials in patients with extubation failure. NIPPV reduced the need for reintubation, ventilator associated pneumonia, need for tracheostomy and ICU mortality.[74, 75, 77] Notably, patients with hypercapnic respiratory failure (mainly COPD) were benefitted the most.

Currently available data suggest that the potential effectiveness of NIPPV for facilitating ventilator weaning and early extubation varies across patient population and that the benefit seems greatest for COPD patients.[41] However, early indiscriminate use in all patients with risk factors is discouraged. Patients with extubation failure treated with NIPPV should be closely monitored and delays in needed intubation be avoided. Further studies are required to better identify those subcategories of patients with non-COPD respiratory failure who are most likely to benefit from NIPPV.

Palliative Care and Do-Not-Intubate Status

NIV may be particularly useful in patients reporting to the emergency room for ARF, with a Do-Not-Intubate (DNI) status, due to advanced age or other critical conditions. There are very few studies which have addressed this issue.[78-80] The current evidence suggests that if the patient and/or family desire prolonged survival, the NIPPV use should be reserved primarily for COPD and congestive heart failure patients.[23] On the other hand, if the goal is to palliate, relieve dyspnea or to delay death, then NIPPV can be used for other

TABLE 141.4: NIPPV for various types of acute respiratory failure (ARF): Evidence for efficacy and strength of recommendation

Type of ARF	*Level of Evidence*[a]	*Strength of Recommendation*[b]
Hypercapnic respiratory failure		
COPD exacerbation	A	Recommended
Asthma	C	Option
Facilitation of extubation (COPD)	A	Guideline
Hypoxemic respiratory failure		
Cardiogenic pulmonary edema	A	Recommended
Pneumonia	C	Option
tALI/ARDS	C	Option
Immunocompromised	A	Recommended
Postoperative respiratory failure	B	Guideline
Extubation failure	C	Guideline
Do-not-intubate status	C	Guideline
Preintubation oxygenation	B	Option
Facilitation of bronchoscopy	B	Guideline

COPD, chronic obstructive pulmonary disease; ALI, acute lung injury; ARDS, acute respiratory distress syndrome.

[a]A – supported by multiple randomized controlled trials and meta-analyses; B – supported by more than one randomized, controlled trial or case control series or cohort studies; C - case series or experts' consensus/opinion; *b* recommended - first choice for ventilatory support in selected patients; Guideline - can be used in appropriate patients with careful monitoring; Option - suitable for a very carefully selected minority of patients under close monitoring.

diagnoses as well.[23] However, it should be reassessed frequently and stopped if the goal of palliation is not being met.

Other ICU Applications of NIPPV

Preoxygenation Before Intubation

Preoxygenation by face mask is standard of care for improving the oxygen status for the patients requiring endotracheal intubation. NIPPV has been tried by few intensive care providers considering the fact that it has the potential to improve oxygenation more effectively than oxygen by face mask.[81, 82] It was also noticed that NIPPV might be a useful preoxygenation technique in the hypoxemic critically-ill patient. However, the current evidence is insufficient to suggest the routine use of NIPPV for this purpose and further studies are required before reaching any conclusion.

Before Fiberoptic Bronchoscopy

Fiberoptic Bronchoscopy (FOB) is an important tool for determining the etiological diagnosis of pneumonia. Arterial oxygen tension routinely decreases by 10 mm Hg to 20 mm Hg in patients after they undergo uncomplicated FOB, may complicate hypoxemia in patients with already compromised oxygen status which puts them on high risk for developing respiratory failure or serious cardiac arrhythmias. NIPPV seems a logical approach in such situations. There is some data to suggest that its use is associated with improved oxygenation and reduces post-procedure respiratory failure in patients with severe hypoxemia undergoing bronchoscopy.[83-85] However, the ICU team must be prepared for the possibility of emergent intubation.

Chronic Ventilation Failure

Chronic ventilation failure is observed in many conditions, including the chest wall diseases, neuromuscular disease and sleep apneas. Mechanical ventilatory support in the form of NIPPV, especially at night, may be helpful in improving ventilation in these conditions. The benefits of this modality include a reduction in need of hospitalization for respiratory illness, improvement in daytime arterial blood gases and respiratory muscle strength and improvement in activities of daily living.[86-89] Data also suggest a good long-term survival benefits of home ventilation with NIPPV.[90] For sleep apnea syndrome, NIPPV is the standard modality of therapy.

CONCLUSION

The role of NIPPV in the management of acute respiratory failure has been further clarified in the recent years (Table 141.4). Evidence is strong to support its use in the initial management of acute respiratory failure in patients with COPD exacerbations, acute cardiogenic pulmonary edema, in immune-compromised state and to facilitate extubation in patients with COPD with failed spontaneous breathing trials. A trial of NIPPV is justified in patients with asthma exacerbations, postoperative respiratory failure, extubation failure or a 'do not resuscitate' status. Supporting evidence for these indications is not strong; they should be carefully selected according to available guidelines and clinical judgment. The response to NIPPV after the first hour or two is the best predictor of eventual outcome, if the patient does not have a favorable initial response to NIPPV, the clinician should consider intubation.

Blood Gas Monitoring*

Chandana Reddy, R Agarwal

INTRODUCTION

Monitoring of arterial blood gases is fundamental to respiratory critical care and oxygen therapy. It is important to recognize gas abnormalities before the appearance of clinical symptoms or signs. A patient may appear to be well oxygenated but may have a low PaO_2 values on blood gas measurements. Therapeutic interventions are required after careful monitoring of blood gases. Blood sample is usually obtained from the radial artery for this purpose. Venous sample though easy and safer to obtain, is not helpful for blood gas monitoring. Blood sample from any artery represents the sample from the left ventricle. On the other hand, venous sample is affected by the metabolism, blood flow and many other factors of different tissues. However, central venous samples have been shown to correlate well with arterial samples with respect to pH, PCO_2 and base excess in mechanically ventilated trauma patients to reach clinically reliable conclusions, but central venous sample cannot substitute arterial samples for resuscitation and management. This chapter will review the technical aspects of both invasive (arterial blood gas analysis) and noninvasive (pulse oximetry and capnography) blood gas monitoring.

INVASIVE TECHNIQUE

Arterial Sampling

Radial artery is the most commonly used site to obtain a sample for arterial blood gas analysis. This is because the radial artery is superficial and easily accessible. Moreover, there is a good collateral vascular network minimizing the risk of vascular interruption in case of complications such as vascular spasm, intraluminal clotting or periarterial hematoma formation which can compromise the blood supply. Radial artery can also be fixed against the radius bone for obtaining sample, and compressed in case of continued ooze. If radial arteries are not available for sampling, other sites such as dorsalis pedis, femoral and brachial arteries should be tried.

It is important to ensure adequate collateral circulation before performing an arterial puncture. In case of the upper extremity, this can be done with the help of a simple and reliable test, the Allen's maneuver. In this, the hand is clenched to form a fist; pressure is applied to obstruct the radial and ulnar arteries at the wrist. The hand is then relaxed (but not fully extended) when the palm and finger are seen to blanch. Thereafter, the pressure from ulnar artery is removed. The thumb and index finger get flushed within 15 seconds, followed by flushing of the entire hand. This is a positive Allen's test indicating adequacy of collateral circulation, i.e. ulnar artery alone is capable of supplying the hand. If the test is negative, it implies the inability of ulnar artery to supply the entire hand. In this situation, the radial artery should not be used for arterial puncture.

In an uncooperative or unconscious patient who cannot clench the fist, the test is done in a similar fashion by obstructing both the arteries, raising the patient's hand above the level of the heart until balancing occurs. The hand is then lowered below the level of the heart and pressure removed from the ulnar artery.

*SK Jindal, R Agarwal. Oxygen Therapy. In: Chandana Reddy, R Agarwal (Eds). Blood Gas Monitoring, 2nd edition. New Delhi: Jaypee Brothers Medical Publishers; 2008.

Technique for Arterial Puncture

The process is explained to the patient, both radial and ulnar arteries palpated and Allen's test applied.

1. A 20 or 21 gauge needle and a glass syringe is taken and 0.2 ml (just enough to smear the inner aspect of the syringe) of 1,000 U/ml heparin is drawn into the syringe. Errors in PaO_2 of up to 6% in two minutes and 16% in 30 to 60 minutes due to exchange of O_2 from plastic syringes have been reported. Hence, glass syringes are generally preferred to plastic syringes unless analysis is done immediately.
2. The wrist is stabilized in the position in which maximum pulsations are felt.
3. The skin is sterilized at the puncture site and a small skin wheal is raised with a local anesthetic.
4. The radial artery is then punctured keeping the needle at a minimum angle of about 30 to 40 degrees to the artery and slowly advancing the needle in one plane. Once the artery is punctured, the blood will enter the syringe.
5. If the needle has completely gone through the artery, its tip is slowly withdrawn until it is once again in the lumen as indicated by the free flowing blood through the needle.
6. After the required amount (2–4 ml) of blood has filled the syringe, the needle is withdrawn and firm pressure is applied at the puncture site for a minimum of two minutes. The pulse distal to the pressure site is palpated to ensure arterial patency.
7. The syringe is then held vertically and air bubbles removed. The needle is then replaced by a syringe cap, the syringe rolled between palms of hand and immersed in a bag of ice and sent to the laboratory.

Arterial Cannulation

Most patients requiring critical care need repeated arterial punctures and many intensivists prefer indwelling arterial catheters/cannulae to repeated punctures. With the availability of an arterial cannula, samples can be immediately and as repeatedly drawn as required. It is also useful in patients whose cardiopulmonary status is unstable. The preanalytical errors related to improper sampling, handling and storage are minimal with samples obtained from arterial cannulae. In addition, the arterial cannulae can be used for systemic blood pressure monitoring and to obtain blood samples for other numerous clinical estimations such as electrolytes, urea, creatinine, etc.

However, arterial cannulation is not without risks. There is an increased incidence of diminished or absent blood flow through the cannulated artery. This is often reversible, although necrosis and loss of tissue have been reported in some cases. Local infection and systemic sepsis can also occur, but the incidence is believed to be no more than that with venous cannulation. Another method to obtain arterial blood, especially in infants and young children, is the arterialized earlobe capillary blood sample (ELCS) which shows strong agreement with arterial blood pH and $PaCO_2$. Simultaneous measurements of oxygen saturation through pulse oximetry may also improve the accuracy of ELCS for PaO_2 assessment.

Measurement Techniques

Measurement of blood pH, PaO_2 or $PaCO_2$ is done with the help of an electrode. It consists of an anode and a cathode immersed in an electrolyte solution. The flow of electrons (electric current) occurs from one point to another in response to a potential difference between the two points. The difference called voltage is measured with a voltmeter. The voltage can be varied predictably with the help of an electric device called potentiometer. A brief account of the different electrodes used for blood gas analysis is described below. Both pH and CO_2 electrodes employ a measuring chemical half-cell of silver-silver chloride solution (to measure small potential differences accompanying pH changes) and a reference half-cell to supply a constant reference voltage.

Oxygen Analysis

There are several techniques to analyze oxygen in the dissolved form which include manometric and volumetric measurements, chemiluminescence method, gas chromatography, physical methods using paramagnetic properties of oxygen and electrochemical techniques. It is the membrane covered oxygen electrode employing the principle of polarography which is most useful and employed in clinical laboratories.

Polarographic electrode for O_2 (Clark electrode) utilizes the principle of chemical reduction of oxygen, i.e. oxygen is dissolved in an aqueous medium and exposed to a polarizing voltage at a cathode wherein the following reaction takes place:

$$O_2 + 2(H_2O) + 4 \text{ electrons } (e') \rightarrow 4\ OH^-$$

The electrode consists of a silver anode and a platinum cathode. The silver anode is immersed in a potassium chloride solution. The chloride ion will react with the silver anode to form silver chloride producing a constant flow of electrons. The adjacent platinum cathode reacts chemically with oxygen to form hydroxyl (OH^-) ions. This reduction reaction uses the electrons. The amount of oxygen reduced is strictly proportional to the number of electrons used in the cathode reaction. The change in electron flow (i.e. current) between the anode and the cathode is measure of the amount of oxygen.

The electrode system is covered by a polypropylene membrane which allows a slow diffusion of oxygen from the blood from into the electrode. The membrane is a slow diffusion membrane to prevent oxygen depletion during the measurement. The ease with which oxygen molecules can pass through the membrane depends upon its permeability coefficient expressed in terms of the number of moles of the gas passing through a specific area and thickness at a given temperature and pressure difference across the membrane.

A galvanic electrode has also been used for oxygen analysis. It is based on a principle similar to the Clark electrode. The voltage for cathode reduction is produced internally by the galvanic cell. The cathode is usually composed of gold, the anode of lead and the electrolyte solution is potassium hydroxide.

Some of the technical difficulties in using the polarographic method of gas analysis include the alteration in the electrolyte layer thickness, changes in electrolyte concentration causing dryness, deposition of silver on the platinum cathode, artifacts due to the presence of gas bubbles in solution and changes in the sensitivity of the membrane. The response time, i.e. the time required in sensitivity of the membrane or the time required for the output to change following a change in the partial pressure of oxygen, of the electrode depends upon the membrane thickness and the permeability coefficient. The average 97.5% response time for a 1 ml teflon membrane covered electrodes is 10 seconds while for 1 ml polypropylene it is close to 40 seconds.

Calibration of the electrode is done with an oxygen concentration of 0 percent and either of 12 or 20%. The calibration of gases for PO_2 and PCO_2 are generally combined for purposes of conveniences and economy.

PCO_2 Electrode

PCO_2 is measured with the help of Severinghaus electrode. It utilizes the principle of Henry's law, i.e. the amount of the gas (CO_2) diffusing across a semi-permeable membrane is directly proportional to the pressure gradient, i.e. PCO_2 in contact with the membrane. The PCO_2 electrode consists of a silicon elastic membrane containing a measuring half-cell (silver-silver chloride) and a similar reference half-cell. It is calibrated each time with a gas mixture containing 5% and 10% CO_2 concen-trations. As stated earlier, gas mixture of 5% CO_2 plus 12 or 20% O_2 (remainder nitrogen) and 10% CO_2 plus 90% N_2 can be used to calibrate both O_2 and CO_2 electrodes.

pH Electrode

The modern pH electrode is an ultramicro Sanz electrode consisting of a pH sensitive glass rolled into a fine capillary tube which draws in a very small quantity of blood to be tested. It maintains anaerobic and thermostatic conditions essential for pH measurement. It is important to know the pH of the buffer solution in the measuring half-cell for purposes of calibration. When the measuring half-cell contains the buffer solution with pH of 7.384 the difference between the two half cells is 0.554 pH units and a 33.5 mv potential difference is predicted. Thus, the voltmeter measures 33.5 mv and a slope potentiometer sets the display at 7.384. Two point calibrations are generally sufficient.

NONINVASIVE BLOOD GAS MONITORING

Blood gas analysis requires repeated arterial punctures or cannulation. Several noninvasive methods have emerged in the last quarter of a century as fairly reliable alternatives to arterial sampling.

Oximetry

Oximetry involves the assessment of arterial oxygen saturation. The concept of pulse oximetry is based on three principles (Fig. 142.1).

1. *Spectrophotometry:* Every substance has a unique absorbance spectrum, and the different types of hemoglobin have different absorption spectra. The currently available pulse oximeters consist of a probe containing two small, high intensity monochromatic light emitting diodes (LEDs) that are activated alternatively and emit light at 660 nm (red) and 940 nm (infrared) wavelengths. These two wavelengths are used because oxyhemoglobin and hemoglobin have different absorption spectra-oxyhemoglobin absorbs less light than deoxyhemoglobin in the ultraviolet region, while the reverse occurs in the infrared region.
2. *Lambert-Beer law:* The absorption of light as it passes through a solution is proportional to the concentra-

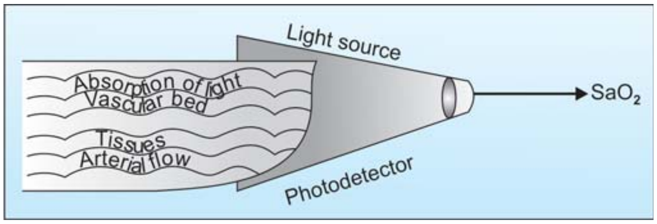

Fig. 142.1: Oximetry-light of known wavelength is passed through the finger tip and measured by the photodetector after absorption by the vascular bed and other tissues (or the finger tip)

tion of those molecules within the solution which have the vibrational frequencies on sympathy with the wavelength of the light.

3. *Optical plethysmography:* The presence of a pulsatile signal generated by the arterial blood that is relatively independent of the nonpulsatile venous and capillary blood and other tissues. Two components of light absorption are associated with pulsatile blood flow; a constant component due to absorption by skin, subcutaneous tissue, venous blood and a pulsatile component due to absorption by the pulsating arterial blood. Comparing the peak and the trough absorbencies, the contribution from nonarterial sources becomes irrelevant. Using changes in absorption during each pulsation the pulse oximeter eliminates the constant component.

CO-oximeter, on the other hand, operates using four different wavelengths and can measure total hemoglobin, oxyhemoglobin, carboxyhemoglobin and methemoglobin, and expresses each as a percentage of the total hemoglobin in a given sample of blood. The value reported by a CO-oximeter is commonly termed "fractional saturation" and is equal to the amount of oxyhemoglobin expressed as a fraction of the amount of total hemoglobin, i.e. the total of all the active and inactive forms of hemoglobin with respect to the oxygen-binding capability (oxyhemoglobin × 100)/(total hemoglobin + oxyhemoglobin + carboxyhemoglobin + methemoglobin).

Pulse oximeters use only two wavelengths and therefore, cannot distinguish between the relative concentrations of each type of hemoglobin derivative present in the blood. A pulse oximeter thus measures the functional saturation, i.e. the relative concentration of oxyhemoglobin expressed as a fraction of the total amount of hemoglobin able to bind oxygen, namely, the ratio of the concentration of oxyhemoglobin and the concentrations of oxyhemoglobin and deoxyhemoglobin. The ratio of absorbencies at these two wavelengths is calibrated empirically against direct measurements of arterial blood oxygen saturation (SaO_2) in volunteers and the resulting calibration algorithm is stored in a digital microprocessor within the pulse oximeter to give the estimated patients' oxygen saturation (SpO_2). At 85% SaO_2, the amount of light absorbed by hemoglobin and oxyhemoglobin is about the same. Hence the normalized amplitudes of the red and infrared signals are equal (i.e. R/LR = 1.0).

In healthy volunteers, oximeters commonly have a mean difference (bias) of less than 2% and a standard deviation (precision) of more than 3% when SaO_2 is 90% or above. Comparable results have also been obtained in critically ill patients with good arterial perfusion. Accuracy of pulse oximeters deteriorates when SaO_2 falls to 80% or less. Most manufacturers report accuracy to within ± 2% for SpO_2 70% to 100 percent, and ± 3 percent for SpO_2 50 to 70%, with no reported accuracy below 50% saturation. There can also be a delay between a change in SpO_2 and the display of that change, and this depends on the signal averaging time, circulation time and the site of the oximeter probe. In general, finger probes are slower (24–35 sec) than earlobe probes (10–20 sec).

Limitations

Pulse oximeters have several limitations, which need to be considered while interpreting SpO_2.

1. They estimate the arterial oxygen saturation (SaO_2) and not the arterial oxygen tension (PaO_2). Pulse oximeters measure SaO_2 that is physiologically related to arterial oxygen tension PaO_2 according to the oxygen-hemoglobin dissociation curve. It is known that because of the sigmoid shape of the oxygen dissociation curve, large changes in PaO_2 may occur in the upper and lower horizontal portions of the curve with minimal changes in the SaO_2. The oxygen-hemoglobin dissociation curve is flattened at saturation values less than 90 to 95% and errors of only a few % in SaO_2 measurements could easily represent a large and significant error in the oxygen tension values. Therefore, pulse oximeters are not accurate enough to safeguard against hyperoxia in neonates at risk of retrolental fibroplasia. Factors that affect the oxygen hemoglobin dissociation curve such as pH, temperature, $PaCO_2$ affect the relationship between oxygen saturation and PaO_2. Pulse oximeters also give us no information regarding the acid-base or the ventilatory status of the patient and hence should not be used as an alternative to blood gas monitoring.

2. Low perfusion states such as hypotension, vasoconstriction, hypothermia or cardiopulmonary bypass and cardiac arrest, produce a signal that is too small to be processed and may make it difficult for the sensor to distinguish a true signal from background noise. Increased venous pulsations as seen in right heart failure can lead to artificially lower SpO_2 readings.
3. The presence of abnormal hemoglobins can lead to erroneous pulse oximetry measurements. At 940 nm, carboxyhemoglobin has minimal light absorption, while at 660 nm, its absorption coefficient is similar to oxyhemoglobin thus in the presence of elevated carboxyhemoglobin levels, oximetry overestimates the SpO_2. Methemoglobin contributes to light absorption at both 660 nm and 940 nm. As the concentration of methemoglobin increases, red and infrared light absorptions increase driving the ratio towards unity which correlates with a saturation of 85%. The difference in the optical absorbance of adult and fetal hemoglobins is too small (<3%) to affect the clinical accuracy of pulse oximetry measurements.
4. Nail polishes, specifically blue, green or black colors have light absorbance near 660 nm and affect the measured SpO_2 leading to falsely low readings. Most studies indicate that the concentration of hemoglobin does not affect the pulse oximeter reading until the hematocrit reaches values less than 10%. Polycythemia, on the other hand, does not affect SpO_2. A number of dyes and pigments can interfere with the accuracy of pulse oximetry. Hyperbilirubinemia has not been shown to affect SpO_2 and in one study, bilirubin levels up to 30.6 mg/dl did not affect the accuracy of pulse oximeter.
5. The readings of pulse oximeters may be affected by high frequency radio interference from electrocautery units and high-intensity light sources such as infrared, xenon and fluorescent lamps. Motion artifact continues to be a significant source of error and false alarms.

Clinical Applications

Pulse oximetry is a noninvasive, relatively inexpensive way to measure and continuously monitor oxygen saturation (Fig. 142.2). Pulse oximetry is widely used during anesthesia, surgery, critical care, hypoxemia screening, exercise and transport from the operating room to the recovery room and in the emergency room. The availability of small, lightweight optical sensors makes SpO_2 monitoring, especially applicable for preterm neonates, pediatric and ambulatory patients. Easy application and fast response time of pulse oximeter helps in monitoring patients during procedures like bronchoscopy, endoscopy, cardiac catheterization, exercise testing and sleep studies. They are commonly used during labor and delivery for both the mother and infant. In critically ill patients, noninvasive monitoring can decrease the distress caused by repeated arterial punctures and assist in titrating the FiO_2 and ventilatory settings. Continuous monitoring also provides information on trends in the patient's condition, to assist the clinician in assessing the response to therapeutic procedures. Hypoxemia is detected more frequently and early during anesthesia and in the recovery rooms with the use of pulse oximetry. Bronchospasm, atelectasis, and bradycardia can be detected more frequently in the group monitored by pulse oximeters. It is also a valuable tool in palliative and supportive care for patients with end stage diseases to determine the need to prescribe or to withhold oxygen therapy.

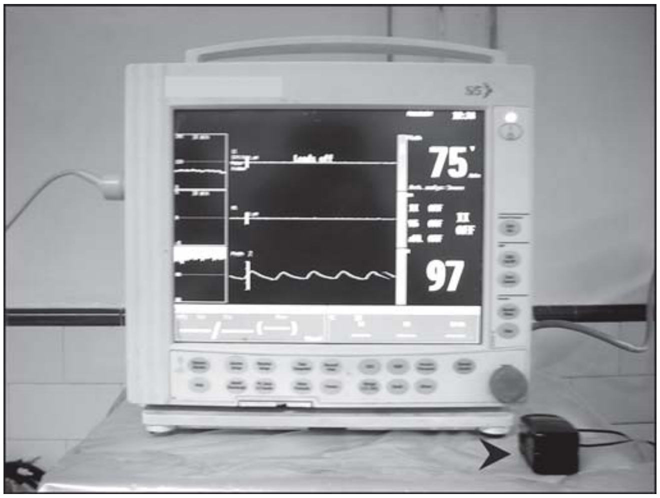

Fig. 142.2: A commonly used pulse oximeter used to continuously monitor SaO_2. The arrow depicts a portable pube oximeter, which can be easily carried around

Generally, the accuracy of most noninvasive pulse oximeters is acceptable for a wide range of clinical applications. Pulse oximetry has replaced transcutaneous oxygen tension monitoring in neonatal intensive care. Intrapartum fetal oximetry is also shown to compare well with fetal scalp blood gas assessment in neonatal management.

Recognizing the above-mentioned limitations and applying appropriate corrective interventions are essential to optimize the clinical use of pulse oximeters. To overcome some of the limitations of pulse oximetry from finger, ear or toe where the pulsatile flow is more easily compromised, esophagus has emerged as another alternative site for continuous monitoring in cases of poor peripheral circulation.

Transcutaneous Oxygen Measurement

Partial pressure of oxygen in blood perfusing the skin ($PtcO_2$) has been used as an estimate of arterial PO_2. This can be done using a modified Clarke electrode which uses a platinum cathode and a silver anode in a potassium chloride solution. Oxygen diffuses from the skin across the membrane to the electrode and reacts with the electrons provided by the anode. The resulting current generated is proportional to the PaO_2. Gas exchange at the skin surface is dependent on the cutaneous blood flow and metabolism. Application of local heat (40–45°C) increases the local blood flow and decreases the influence of cutaneous blood flow on $PtcO_2$ measurement. Actual PaO_2 rather than SpO_2 is measured and hence can be used to monitor hyperoxemia and prevent its complications especially in neonates. Values are not affected by abnormal hemoglobins. $PtcO_2$ can be used to assess shunt in a patient on supplemental oxygen, detect onset of hemodynamic instability and limb ischemia. Oxygen reaches the surface after traversing the epidermis. Skin also consumes oxygen, so there is always a gradient between $PtcO_2$ and PaO_2. Response of $PtcO_2$ electrode to a rapidly changing PaO_2 is slow. These problems are minimized in neonates and infants in view of the thin skin with lower metabolism. Local heating may lead to thermal injury to the skin and the site of the electrodes may need to be changed frequently. Accuracy is affected by low perfusion states, hemoglobin concentration, capillary density, and hydration of the epidermis. It has a potential role in monitoring in neonates and infants in critical care, but in adults the use of $PtcO_2$ measurement is limited. Unpredictable correlation of $PtcO_2$ with PaO_2, slow response characteristics and the need for 3 to 4 hourly site changes, limit its use for monitoring during anesthesia, exercise and sleep studies.

Transcutaneous PCO_2 Measurement

Transcutaneous CO_2 ($PtcCO_2$) measurement reflects $PaCO_2$ in the arterial blood in a similar fashion as the $PtcO_2$ which reflects PaO_2. The electrode senses the PCO_2 by monitoring changes in either the pH of bicarbonate containing electrolyte solution or the infrared absorption from a sample chamber. In view of a much higher solubility of CO_2 in the tissues, $PtcO_2$ estimation is less dependent upon cutaneous perfusion than $PtcCO_2$. Therefore heating the skin to 40°C suffices. The electrode can be left in place for up to 48 hours without the risk of thermal injury. Heating causes a temperature dependent rise in the PCO_2 and an overestimation of $PaCO_2$.

Transcutaneous PCO_2 measurement has been also employed for apnea test. In brain dead patients, a $PtcO_2$ of 60 mm Hg accurately predicts a $PaCO_2$ of 60 mm Hg allowing a reduction in the duration of apnea test. Combined O_2-CO_2 electrodes are also available. Since the OH– ions produced by O_2 reduction accumulate in these electrodes, there is a problem of change in the pH of the electrolyte solution for PCO_2 sensing. Some of the electrodes are designed to consume the accumulated OH– ions preventing the pH shift.

Capnography

Continuous waveform display of the changes in the concentration of carbon dioxide throughout the ventilatory cycle is called capnography. Capnography was developed in 1943 and introduced to clinical practice in the early 1950s. Commonly, capnography uses the principle of infrared light absorption (infrared spectro-metry) or mass spectrometry. The first method depends on the concept that CO_2 strongly absorbs infrared light at a wavelength of 4280 nm. This infrared radiation passes through the sample chamber where it is absorbed by CO_2 and the remaining unabsorbed radiation is focused onto a detector with a semiconductor that creates an electrical signal. The concentration of CO_2 is directly proportional to the amount of infrared light absorbed and higher the CO_2 concentration in the gas mixture the more infrared radiation is absorbed and less arrives at the detector. This method allows for real time, continuous measurement, and display of PCO_2 with a delay time of approximately 0.25 second.

The end-tidal ($PetCO_2$) CO_2 monitors can be categorized as mainstream or sidestream variety depending upon the gas sampling technique. Mainstream analyzers are placed in the airway circuit usually between the end of the endotracheal tube and the Y connection. They provide continuous monitoring and the response is rapid. They are heavy, may cause kinking or dislodgement of the endotracheal tube and increase the dead space. The sensors can be disrupted by humidity and secretions and heating is required to prevent condensation. The second method is the sidestream analyzer, in which the gas sample is aspirated from the breathing circuit through a small bore tube to a remote analyzer. Time delay, loss of expired tidal volume and clogging by pulmonary

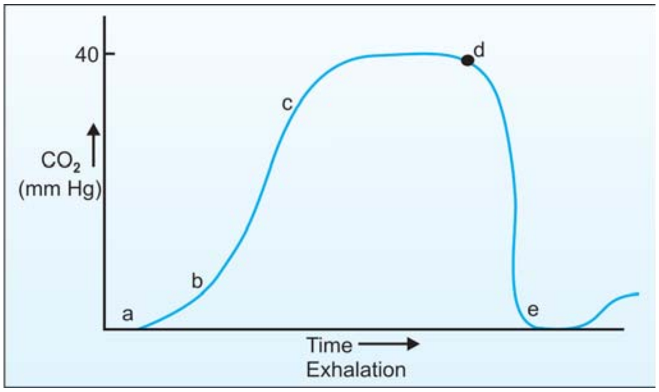

Fig. 142.3: A normal capnogram (see text for details)

secretions are the main disadvantages. It may also be contaminated by ambient air.

The capnogram during expiration is normally divided into three phases (Fig. 142.3). The first phase: (a) represents the gas from the anatomical dead space (trachea) that is free of CO_2. In the second phase (b) the curve rises sharply as the alveolar gas that contains CO_2 mixes with the dead space. This represents emptying of rapidly emptying alveolar spaces. As expiration continues (c) more and more of the alveoli empty and CO_2 concentration rises rapidly until a plateau (d) that essentially represents alveolar gas, is reached (phase 3). When inspiration starts the CO_2 level drops sharply and there is a rapid down-stroke of the curve to zero (e). The highest CO_2 tension measured during the plateau phase (i.e. the point at which the plateau ends just before inspiration) is referred to as the end tidal CO_2 concentration ($PetCO_2$).

$PetCO_2$ is commonly used to estimate $PaCO_2$ quantitatively; however the $PetCO_2$ is less than the $PaCO_2$, and in normal individuals P (a-et) CO_2 gradient ranges between 2 and 5 mm Hg. This is because of the normal physiological dead space. The $PetCO_2$ can be affected by changes in alveolar ventilation, CO_2 production (metabolism) and transport (perfusion). Capnography is helpful in ensuring adequacy of pulmonary ventilation, assessing changes in pulmonary blood flow and physiological dead space, and detecting the addition of CO_2 to the systemic circulation. $PetCO_2$ can increase in conditions with increased production of CO_2 (fever, sepsis), decreased ventilation or equipment malfunction. Decrease in $PetCO_2$ with increase in the gradient can occur secondary to increased dead space (as during hypotension, pulmonary emboli, and cardiac shunts), incomplete alveolar emptying, decreased CO_2 production or equipment malfunction.

$PetCO_2$ can be used for continuous noninvasive monitoring of $PaCO_2$ as long as the capnogram waveform remains unchanged, the temperature remains constant and the ventilatory and cardiovascular functions are stable. A normal capnogram with a large difference between $PetCO_2$ and $PaCO_2$ indicates substantial physiologic dead space.

Capnography has been shown to be useful during intubation to ensure tracheal rather than esophageal intubation. CO_2 is primarily eliminated from the lung and the concentration of CO_2 in the stomach is negligible, so with tracheal intubation the $PetCO_2$ is high (20-45 mm Hg) and remains so, whereas with esophageal intubation the $PetCO_2$ is usually zero and the waveform disappears. Capnography is also helpful in recognizing disconnection from ventilation system, accidental extubation and airway obstruction. Capnography provides a simple, noninvasive, rapid continuous monitor and can be helpful in patients undergoing elective surgery under general anesthesia, patients receiving hyperventilation to decrease intracerebral edema, and those requiring apnea monitoring. It has also been helpful as a prognostic tool during cardiopulmonary resuscitation (CPR). Sudden increase in $PetCO_2$ indicates successful (CPR) with return of spontaneous circulation. Falsely low $PetCO_2$ can occur due to leaks in the sampling system or circuit.

Capnographic waveform changes are also important and may be characteristic of certain clinical situations; hence it is essential to monitor the waveform tracing in addition to the numerical value of $PetCO_2$. An elevation of baseline indicates clinically important rebreathing of exhaled air secondary to malfunction of expiratory value or exhaustion of CO_2 absorbent. Delayed up-stroke with flattening of phase 2 and blurring of the distinction between phase 2 and 3 is seen in obstructive pulmonary diseases. Restrictive lung diseases cause irregularity in the plateau due to uneven alveolar emptying.

Capnography in the intensive care unit (Fig. 142.4) during mechanical ventilation can help in detecting the development of pulmonary emboli (rapid fall in $PetCO_2$) or a pneumothorax (inability to maintain a plateau). Capnography can also be used to measure the physiological dead space using mixed expired CO_2 tension ($PetCO_2$). It can help in determining the best positive end-expiratory pressure (PEEP) during mechanical ventilation. The hypothesis is that PEEP decreases the dead space by recruiting alveoli, whereas higher PEEP leads to over distention of the alveoli that can increase the dead space. The smallest Pa-etCO_2 gradient coincides with the maximal recruitment of the alveoli without over distention and the least shunt, and hence the PEEP level can be adjusted while monitoring the Pa-etCO_2 gradient in addition to other parameters.

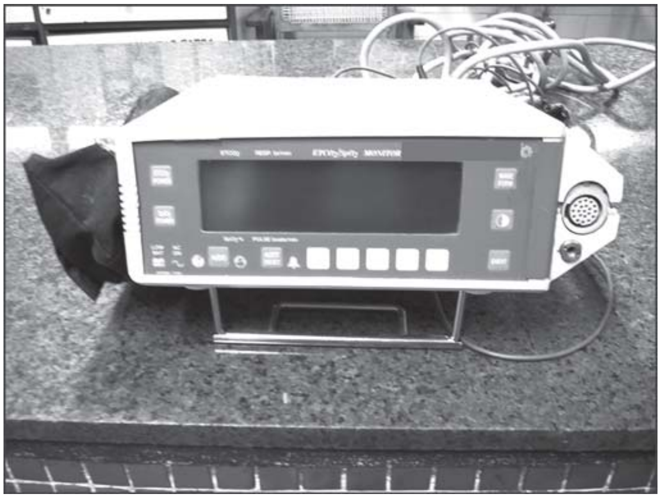

Fig. 142.4: Capnography instrument used in ICU

Capnography, however, cannot be reliably used for patients wearing face masks and nasal cannulae. The readings should be interpreted with caution in critically ill patients and should be periodically confirmed by an arterial blood gas analysis.

Cutaneous Capnography

Ankur Mehta, Prashant Chhajed

INTRODUCTION

Cutaneous carbon dioxide tension ($PcCO_2$) measurement is used as a noninvasive surrogate measure of $PaCO_2$, which is used either to estimate $PaCO_2$ or to determine trend changes in $PaCO_2$. Although $PcCO_2$ monitoring has been available since the 1970s, it is not used as commonly as one might expect, this has been mainly attributed to technical factors. The special features of $PcCO_2$ monitoring are that it and averages out breath-by-breath variations and has almost no inherent "noise" or variability so that it is often found to be the best trend monitor for detecting small changes in $PaCO_2$.[1] Arterial blood gas analysis is the "gold standard" method to measure the arterial partial pressure of carbon dioxide ($PaCO_2$). However, arterial sampling including arterial catheterization is invasive and expensive. Intermittent arterial puncture is also associated with pain and discomfort for the patient.

To evaluate the accuracy of transcutaneous PCO_2 ($PtcCO_2$) as a surrogate for $PaCO_2$, in a cohort of adult critically ill patients in a medical Intensive Care Unit (ICU). Prospective observational study comparing paired measures of transcutaneous and arterial PCO_2. A total of 189 paired PCO_2 measures were obtained. Twenty-one were excluded from analysis, because profound skin vasoconstriction was present. Finally, 168 were analysed, including 137 obtained during mechanical ventilation and 82 under catecholamine treatment. Body temperature was below 36°C for 27 measurements. Mean duration of monitoring was 17+/-17 h. The mean difference between $PaCO_2$ and $PtcCO_2$ was -0.2+/-4.6 mm Hg with a tight correlation (R(2) = 0.92, p > 0.01). PCO_2 bias did not significantly change among three successive measurements. Changes in $PaCO_2$ and in $PtcCO_2$ between two blood samples were well correlated (R(2) = 0.78, p > 0.01). Variations of more than 8 mm Hg in $PtcCO_2$ had 86% sensitivity and 80% specificity to correctly predict similar changes in $PaCO_2$ in the same direction. Catecholamine dose or respiratory support did not affect $PtcCO_2$ accuracy. Hypothermia had only a small effect on accuracy. No complication related to the prolonged use of the sensor was observed. Transcutaneous PCO_2 provided a safe and reliable trend-monitoring tool, provided there was no major vaso-constriction.[2]

When first introduced, $PcCO_2$ measurement was combined with the measurement of PcO_2. Cutaneous oxygen (PcO_2) and $PcCO_2$ monitoring were introduced to provide noninvasive measures of the arterial partial pressure of oxygen (PaO_2) and $PaCO_2$.[3,4]

Pulse oximetry came to use in the mid eighties and quickly replaced transcutaneous blood gas analysis. Oxygen saturation measured with a pulse oximeter (SpO_2) provides a surrogate measure of arterial oxygen saturation. However, measurement of SpO_2 does not completely reflect ventilation. Due to the S-shape of the oxygen dissociation curve, hypoventilation with a decrease in the PaO_2 may remain unnoticed over a period of time. Furthermore, with the administration of supplemental oxygen during various medical procedures carried out under sedation, although the patient would have adequate arterial saturation, one would nevertheless remain unaware of the adverse physiological trend that may be reflected by changes in the $PaCO_2$. Therefore, taking this limitation of pulse oximetry into consideration, some new generation monitors have now come up with combining cutaneous $PcCO_2$ measurement along with pulse oximetry in one sensor.[5,7] With evolution in technology, there has been considerable progress in the technical aspects of $PcCO_2$ monitoring in the last few years.

Comparison with Arterial Blood Gas

Arterial blood gas analysis is the gold standard for measuring the arterial partial pressure of carbon dioxide ($PaCO_2$). As this measurement is intermittent, an arterial catheterization is often performed to allow repeated sampling. Arterial blood gas analysis or arterial catheterization can be time consuming, painful for the patient and bears the risk of catheter-related infection, hemorrhage, ischemia, arteriovenous fistula and pseudoaneurysm formation.[8] In addition, there is a risk of preanalytical errors when venous blood is sampled air bubbles are trapped in the syringe, or the specimens are transported via pneumatic tube delivery systems which can potentially lead to false measurements results.[9-11] In patients with endotracheal intubation, the measurement of end-tidal carbon dioxide tension ($EtCO_2$) is routinely performed and this has shown to correlate with arterial partial pressure of carbon dioxide. $PaCO_2$.[12,13] However, $EtCO_2$ may inaccurately estimate $PaCO_2$ in case of ventilation/perfusion mismatch found in patients with obstructive lung disease and acute respiratory distress syndrome.[14,15]

Measurement of $EtCO_2$ using side-stream capnography in nonintubated sedated patients has the risk of oral leakage when patients alternate between oral and nasal breathing and can yield incorrect measurements.[16] Pulse oximetry provides a continuous and an accurate measurement of hemoglobin saturation with oxygen.[17] However, it is a good surrogate only for oxygenation, and does not adequately reflect ventilation due to lack of carbon dioxide measurement.[18] Cutaneous carbon dioxide tension monitoring has been available for several years, but has not found common usage in several fields of clinical practice due to perceptions of being time and work intensive, difficult calibration procedures, long equilibration time and the necessity to frequently change the skin site of the sensor to avoid thermal injury to the skin.[19,20] Recently developed devices have features like automatic calibration, shorter response and equilibration times.

Development of $PcCO_2$ Monitoring Devices

The frequent change in sensor membranes and long calibration procedures have given $PcCO_2$ monitoring a reputation of being more labor intensive.[21] Some authors have attributed slow response time of the electrodes and the reflex vasoconstriction of the skin vessels related to hyperventilation as factors making transcutaneous measurements unreliable for monitoring blood gas changes.[22] With evolution in technology, considerable progress has been made in shortening the response times, calibration and equilibration times, reducing the temperature of the sensor to 42°C and analog to digital conversion of the signal in the sensor itself.[5] Until recently, the $PcCO_2$ sensors were heated between 43 and 45°C. Skin injuries have not been uncommon at these temperatures.[23] The newer generation $PcCO_2$ sensors, which are heated to 42°C, can be safely kept continuously for periods of up to 8 hours with minimal risk of thermal skin injury and the sensor sites do not need to be changed frequently.[24]

Measurement of $PcCO_2$ is possible because carbon dioxide has high tissue solubility and diffuses through the skin. It can be performed using monitors which employ the Severinghaus electrode or infrared sensors.[20] Most $PcCO_2$ monitors are based on Severinghaus principle. $PcCO_2$ is performed by placing a heated surface electrode on the skin. Application of heat to the skin surface increases blood flow in the arteriovenous anastomoses and the venous plexus. When this occurs, capillary blood is arterialized (Table 143.1).[21] Adapted from the article: The Design, Use, and Results of

PCO_2 range	1–200 mm Hg (0.1–27 kPa)
In vitro response time (10–90%)	50 s
Arterialization time after application	3-10 min, depending on the site of the sensor on the skin

Transcutaneous Carbon Dioxide Analysis: Current and Future Directions.[25]

Site for Measurement

The ear lobe sensor has been reported to detect the SpO_2 change, 5 to 37 seconds faster than a finger sensor and the $PcCO_2$ change 9 to 48 seconds faster than a cutaneous sensor fixed at the upper arm.[6] The heated sensor increases the blood flow at the measurement site. The arterialization time of the ear lobe (i.e. the time until the cutaneous value reflects the arterial value) is significantly shorter at the earlobe (2.5 ± 1 min) than at the inner arm (7 ± 2 min).[26,27] Warming the ear lobe with the sensor not only increases the blood flow which is required for $PcCO_2$ measurement but also improves the quality of the SpO_2 signal, which has been questioned at the ear lobe.[21,26,28,29] Digital ear pulse oximetry (part of combined SpO_2 and $PcCO_2$ sensor) has been reported to have shorter SpO_2 response times than conventional, analog ear pulse oximetry. Due to these factors, the delay to the detection of hypoxemia may be shortened. *Other measurement sites: forehead – check papers or abstracts. This becomes particularly important while measurements are sought in infants and neonates as they typically will not have ear lobe to place the sensor.*

Factors Influencing $PcCO_2$ Monitoring

The success of $PcCO_2$ monitoring depends on technical and patient factors. The technical factors which may affect the accuracy of the measurement include an improper application of the sensor membrane, trapped air bubbles in the electrolyte solution under the membrane, damaged sensor membranes, delayed changing of sensor membrane, calibration gas leaks leading to an improper calibration and excessive force on the ear lobule in case of ear clips. The patient factors which may influence $PcCO_2$ values include hypoperfusion at the site of measurement, shock, edema, skin thickness the thickness of the ear lobule for ear clips and the use of vasoconstricting drugs.[4,30] A cardiac index below 1.5 L/min can dramatically increase the $PcCO_2$–$PaCO_2$ gradient.[31] There is also a distinct possibility of occasional errant $PcCO_2$ values, e.g. difference of 8 to 12 mm Hg compared to arterial blood gas analysis.[20]

MEDICAL APPLICATIONS OF $PcCO_2$ MONITORING

End Tidal Carbon Dioxide Monitoring

Measurement of $PetCO_2$ is a noninvasive method of estimating $PaCO_2$. For the estimation of pulmonary dead space, there is an excellent correlation between (1) the difference (gradient) between $PaCO_2$ and the $PetCO_2$, and (2) the ratio between dead space and tidal volume (VD/VT). Its use to confirm correct placement of endotracheal tube in the airway has a sensitivity and specificity of up to 100%. This method cannot be used to detect bronchial or hypopharyngeal misplacements. With the relationship between $PaCO_2$ – $PetCO_2$ and VDS/VT well established, the research in the detection of pulmonary embolism is promising but incomplete.[32]

Advantages of End Tidal Carbon Dioxide Measurements

One of the most common causes of intubation failure is inadvertent esophageal intubation, which can have catastrophic consequences.[32] Direct visualization of the endotracheal tube passing through the vocal cords, endotracheal tube condensation, observation of chest wall movement and auscultation of breath sounds are commonly used clinical signs to aid confirmation of correct endotracheal tube placement. However, as none of these are infallible, the addition of CO_2 detection using the colorimetric device is a very useful adjunct to clinical assessment. The disposable $ETCO_2$ detector significantly decreases the time for clinical determination of endotracheal tube position. The detector also has prognostic value for return of spontaneous circulation and short-term survival in adults and children.[35,36] In adults, none of the patients with colorimetric $ETCO_2$, 2% were successfully resuscitated after cardiopulmonary resuscitation.[33]

Limitation of End Tidal Carbon Dioxide Measurements

Colorimetric $ETCO_2$ detectors cannot detect hypocarbia or hypercarbia, right main stem bronchus intubation or oropharyngeal intubation in spontaneously breathing patients.[33] If the colorimetric detector is contaminated with acidic gastric contents or drugs, such as adrenaline (epinephrine), there is a fixed yellow discoloration and results are unreliable. Humidity decreases the clinical lifespan of the detector from a maximum of two hours (Portex) or 24 hours (Smiths). CO_2 is a product of cellular metabolism and is removed through the circulation and the lungs. Therefore, $ETCO_2$ reflects ventilation, metabolism and circulation.[33] During cardiopulmonary resuscitation, a positive test confirms placement of the endotracheal tube within airway, whereas a negative test indicates either esophageal placement or airway intubation with poor or absent pulmonary blood flow.[34] In this situation, an alternative means of assessing endotracheal tube placement is required.

Neonates requiring venoarterial Extracorporeal Membrane Oxygenation (ECMO) may also potentially show a false negative result with the $ETCO_2$ detector. In this scenario, the membrane oxygenator, bypassing the pulmonary circulation, removes CO_2, resulting in significantly reduced $ETCO_2$. The reliability of end tidal CO_2 measurement, however, is limited, particularly in the presence of parenchymal lung disease or air leakage at the face mask.[35]

Clinical Settings for the Use of Cutaneous Capnography

There are several conditions where $PcCO_2$ monitoring can be useful (Table 143.2). There is an overlap of the clinical indications where both $PcCO_2$ and $PetCO_2$ monitoring may be used. Both these methods have independent indications, sometimes complimentary to each other in patient care.

Use in Emergency Room

Transcutaneous Carbon Dioxide Tension ($TcPCO_2$) monitors offer a noninvasive method of continuous measurement of arterial carbon dioxide tensions. The concordance between the $TcPCO_2$ measurement and the value obtained from arterial blood gas sampling was measured in patients attending the emergency department. A prospective observational cohort study was performed in 49 adult patients who underwent arterial blood gas sampling as a part of their assessment. Blood gas sampling and recording of the $TcPCO_2$ level from the monitor was done simultaneously. Concordance between the two values ($PaCO_2$ and $TcPCO_2$) which was demonstrated using the method described by Bland and Altman with the mean difference of 0.02 kPa (95% CI, 0.11–0.15). The Pearson's correlation coefficient was 0.94 ($p<0.001$) and the Bland-Altman limits of agreement were +/-0.9 kPa. In adult patients, concordance between carbon dioxide measurements by transcutaneous monitor and arterial blood sampling is good. Using the transcutaneous method, patients may be monitored noninvasively which may reduce the need for repeated blood gas sampling.[36]

TABLE 143.2: Clinical applications of $PcCO_2$ monitoring

Operating room – patient monitoring during and after anesthesia

- Intensive care unit
  Neonatal
  Adult critical care
  Monitoring patients receiving noninvasive ventilation
  Guiding mechanical ventilation
  Monitoring of patients after extubation
- Endoscopy under conscious sedation
  Bronchoscopy
  Thoracoscopy
  Gastroscopy/colonoscopy
- Sleep laboratory
  Assessment of alveolar hypoventilation
  Titration of noninvasive ventilation
- Lung function laboratory
  Oxygen titration in patients with severe chronic obstructive pulmonary disease
  Diagnosis of hyperventilation
- Cardiopulmonary exercise testing
- Assessment of hyperventilation response in patients with hypercapnia

Operation Room

$PcCO_2$ monitoring has been shown to provide better estimates of $PaCO_2$ values in patients undergoing various surgical procedures.[30,37-39] Although, $PetCO_2$ may be inaccurate because of ventilation/perfusion mismatch, it has become a standard for monitoring carbon dioxide concentrations during general anesthesia. $PcCO_2$ has been suggested to be a valuable addition to capnography in patients with an increased $PetCO_2/PaCO_2$ difference and in situations in which the continuous, noninvasive and precise control of carbon dioxide level is required (e.g. one lung ventilation). We believe that $PcCO_2$ and $PetCO_2$ monitoring are complementary in many situations. It is unlikely that $PcCO_2$ monitoring will replace $PetCO_2$ monitoring, as $PetCO_2$ allows for detection of life-threatening situations such as accidental esophageal intubation, ventilator disconnection or pulmonary embolism.[37]

The pulse oximetry is widely used to monitor patients postoperatively. Although it accurately measures arterial oxygen saturation, it provides no information on ventilator status. When patients are receiving high concentrations of supplemental oxygen, oxygenation can be maintained with inadequate alveolar ventilation because of the diffusion of oxygen molecules from the airways into the alveoli. In this setting, severe hypercapnia and respiratory acidosis may result in this setting. This phenomenon of apneic oxygenation illustrates a major limitation in monitoring patients postoperatively with the pulse oximetry.[40]

If alveolar ventilation ceases, the PCO_2 increases at a rate of 2.7–4.9 mm Hg per minute.[41] In the absence of supplemental oxygen, the maximal carbon dioxide pressure compatible with life is approximately 100 mm Hg. Beyond this value, there is excessive displacement of alveolar oxygen, leading to lethal hypoxia and death. Oxygenation may be maintained during insufficient or absent ventilation if high concentrations of oxygen are administered. Because of the extraction of oxygen by erythrocyte hemoglobin in the pulmonary capillaries, an oxygen concentration gradient develops between the upper airways and the alveoli. This leads to mass diffusion of oxygen molecules down the airways and into the alveoli, even in the absence of ventilation, however, this process is inadequate to remove carbon dioxide which is thus retained until the buffering capacity of blood and tissues is exceeded and profound respiratory acidosis results. This process is known as diffusion respiration or apneic oxygenation.[40]

Intensive Care Unit

The potential applications of $PcCO_2$ measurement in the ICU include the monitoring of patients receiving mechanical ventilation, noninvasive ventilation and postextubation. The aim in these situations is mainly to monitor the trends of change in $PaCO_2$ by monitoring $PcCO_2$. End tidal CO_2 ($PetCO_2$) is commonly used in patients receiving mechanical ventilation. However, $PetCO_2$ cannot be applied to patients receiving non invasive ventilation because of air flow through the mask. The response time of $PcCO_2$ values to a change in non-invasive ventilation has been shown to be compatible with the aim of clinical monitoring.[20]

Patients with respiratory failure are at risk for worse hypercapnia when off ventilator. Assessment of hypercapnia and changes in arterial PCO_2 are often used to determine whether patient receiving a high level of ventilatory support can be considered for a spontaneous breathing trial (SBT). Transcutaneous PCO_2 measurement is helpful to assess and manage patients during spontaneous breathing trials.[42] Whereas arterial oxygen saturation (SaO_2) is commonly estimated by pulse oximetry, $PaCO_2$ may be estimated from end-tidal carbon dioxide tension[2] or transcutaneous carbon dioxide tension ($PtcCO_2$). Since alterations in ventilation/perfusion matching and the use of noninvasive mask ventilation may reduce the correlation of end-tidal carbon dioxide tension with $PaCO_2$, transcutaneous monitoring of $PtcCO_2$ is increasingly used if the rapid tracking of transient fluctuations of $PaCO_2$ is not essential.

Neonatal Intensive Care Unit

Arterial Oxygen Saturation (SaO_2) and arterial carbon dioxide partial pressure $PaCO_2$ are two of the most important respiratory parameters in the treatment of critically ill neonates. Noninvasive monitoring of these parameters is desirable for continuous estimation of the respiratory status and to reduce blood loss because of repeated blood gas analyses. Transcutaneous measurement of PCO_2 represents a simple and noninvasive technique for continuous monitoring of ventilation.[43]

Pulse oximetry and carbon dioxide pressure measured by capillary arterialized blood gases and a combined transcutaneous carbon dioxide and pulse oximetry ($PtcCO_2$/ SpO_2) monitor were compared in 65 patients (asthma, n = 16, recurrent bronchitis, n = 8, lung infection, n = 8, cystic fibrosis, n = 15, interstitial lung disease, n = 6, neuromuscular disease, n = 12). Daytime capillary arterialized blood gases and nocturnal recording of pulse oximetry and carbon dioxide by means of a combined $PtcCO_2/SpO_2$ monitor were performed in 50 other patients receiving nocturnal noninvasive respiratory support at home. Nocturnal hypercapnia may occur in children receiving nocturnal noninvasive respiratory support at home. Nocturnal pulse oximetry and daytime arterial blood gases are not sufficiently accurate to diagnose nocturnal hypercapnia, underlying the importance of a systematic carbon dioxide monitoring in children receiving noninvasive respiratory support. In the study undertaken shows first, that the values for SpO_2 and $PtcCO_2$ measured by a combined $PtcCO_2/SpO_2$ monitor are reliable in children, and second, that nocturnal hypercapnia is observed in a significant number of children treated at home with nocturnal long-term noninvasive respiratory support. This nocturnal hypoventilation is not associated with clinical symptoms of sleep disordered breathing, nocturnal desaturation, or daytime hypercapnia on capillary arterialized blood gases, underscoring the value of a systematic nocturnal PCO_2 monitoring in children treated by noninvasive respiratory support at home.[44]

Although, the direct measurement of $PaCO_2$ remains the gold standard, it provides only a single measurement of what is often a rapidly changing and evolving clinical picture. Given these concerns, there remains a clinical need for a means to continuously monitor $PaCO_2$ without the need for repeated blood gas analysis. Although, initially introduced into the neonatal intensive care unit; with improvements in the technology, transcutaneous CO_2 monitoring can now be used in infants, children and even adults. When compared with end-tidal carbon dioxide ($ET\text{-}CO_2$) monitoring techniques, transcutaneous CO_2

monitoring has been shown to be equally as accurate in patients with normal respiratory function and more accurate in patients with shunt or ventilation-perfusion inequalities. Transcutaneous CO_2 monitoring can be applied in situations that generally preclude end-tidal CO_2 monitoring such as high frequency ventilation, apnea testing, and noninvasive ventilation. Transcutaneous CO_2 monitoring has also been used in spontaneously breathing children with airway and respiratory issues such as croup and status asthmaticus as well as to monitor metabolic status during treatment of acidosis related to diabetic ketoacidosis. Transcutaneous carbon dioxide monitoring may be a useful adjunct in various clinical scenarios in infants and children. It should be viewed as a complimentary technology and may be used in combination with end-tidal CO_2 monitoring.[45]

Endoscopy Room

Diagnostic and therapeutic endoscopic procedures are now increasingly performed under sedation with supplemental oxygen.[46-48] As discussed earlier, pulse oximetry does not completely reflect the ventilatory status. Respiratory depression often occurs following administration of sedative medication and this may have to be treated with sedation reversal and/or mask ventilation.[49,50]

The British Thoracic Society Guidelines suggest that $PcCO_2$ monitoring may be useful in patients with COPD having hypercapnic respiratory failure.[51] Evans et al. have reported in a study of 22 patients that hypoventilation with significant elevation of $PcCO_2$ occurs during bronchoscopy and provides an earlier indication of respiratory depression during flexible bronchoscopy compared with pulse oximetry.[52] However, they also concluded that $PcCO_2$ analysis was complex. In a recent study, the mean baseline and peak $PcCO_2$ levels were 38 mm Hg and 49 mm Hg, respectively. The mean duration from baseline to peak $PcCO_2$ level was 14 minutes. SpO_2 dropped to ≤ 90% in 15 patients and the mean increase in $PcCO_2$ was 14 mm Hg.[53] Similarly, significant hypoventilation has been reported for the first time in patients undergoing medical thoracoscopy performed under local anesthesia and sedation.[54] The baseline $PcCO_2$ measurement was 39 mm Hg and the peak measurement during the procedure was 50 mm Hg.[54] In a prospective randomized study in patients undergoing colonoscopy, the mean increase in $PcCO_2$ with midazolam was 8.2 mm Hg as compared to 6.6 mm Hg with propofol. The mean difference from initial $PcCO_2$ to that, five minutes after the end of the procedure, was 4 mm Hg with midazolam and 0.9 mm Hg with propofol.[55] The findings of these studies supported that combined $PcCO_2$ and SpO_2 measurements during endoscopy performed under sedation might improve patient safety.

The combined POX/$PcCO_2$ monitoring at the earlobe is a novel approach to detect hypoventilation and therefore might improve patient safety during sedation. It may be used to titrate the administration of sedative drugs to prevent an unintentional slide into deep sedation or anesthesia with the risk of development of apnea. Larger studies, especially with short-acting sedative drugs like propofol, are needed to confirm the clinical benefit of this novel technique.[56] In the study of 33 patients (48% female; mean age B SD 59 B 12.9 years) undergoing colonoscopy under sedation and analgesia with midazolam combined with alfentanil or without any sedation or analgesia shows (1) that values recorded with the combined POX/$PcCO_2$ sensor correlate excellently with blood gas analysis; (2) that in sedated patients undergoing colonoscopy hypoventilation reflected by retention of PCO_2 can easily be detected by the use of a combined POX/$PcCO_2$ ear sensor, and (3) that monitoring with the combined POX/$PcCO_2$ sensor is more specific in the detection of hypoventilation than standard POX alone.[56]

Flexible Bronchoscopy

Flexible bronchoscopy under local anesthesia and sedation is widely performed to diagnose and manage a variety of lung diseases. The purpose of sedation is to facilitate examination of tracheobronchial tree, carry out necessary diagnostic and interventional procedures and provide patient comfort. Oximetry measures the oxygenation of blood and can detect hypoxemia, but it can not detect hypercarbia and hence the adequacy of ventilation.[52] When bronchoscopy is performed under conscious sedation without supplemental oxygen, oxygen desaturation will occur rapidly giving a good indication of ventilator status. However, most centers routinely offers oxygen supplementation during flexible bronchoscopy. Due to the S-shaped curve of the oxygen dissociation curve, in such situation alveolar carbon dioxide tension will have to increase further before significant hypoxemia is manifested.[57] Therefore, a reliable substitute of carbon dioxide arterial tension ($PaCO_2$) measured noninvasively is required as it enhance patient safety during flexible bronchoscopy. Ventilation can be effectively monitored using combined oximetry and cutaneous capnometry.[58]

Patients with chronic obstructive pulmonary disease (COPD) which were defined using the American

Thoracic Society/European Respiratory Society guidelines demonstrates the feasibility of measuring combined oximetry and cutaneous capnography effectively to monitor ventilation during flexible bronchoscopy. Patients with COPD who are not in hypercapnic respiratory failure have a similar risk of hypoxemia and hypercapnia compared with those without COPD during bronchoscopy. The peak $PcCO_2$ is higher in patients with a higher baseline $PcCO_2$ and is associated with lowest SpO_2 during bronchoscopy. Significant hypoxemia is associated with the peak $PcCO_2$ and baseline SpO_2. With the current study results, it is not possible to predict and accurately select a group of patients who should undergo capnography during bronchoscopy. Patients with elevated baseline $PaCO_2$ or a low baseline SpO_2 will have the benefit of better monitoring of ventilation using such a device. Specifically, patients with a longer duration of procedure did not show a different rise in $PcCO_2$ compared with the others. Furthermore, the current authors expected an association of the sedative dose with rise in cutaneous carbon dioxide tension, but that was also not the case. Therefore, future studies need to analyse the different patient groups with regards to the baseline cutaneous carbon dioxide tension to potentially limit the application of cutaneous capnography to only a specific group of patients.[58]

Assessment of Long-Term Oxygen Therapy

Long-term oxygen therapy (LTOT) is used in patients with hypoxemia due to severe obstructive and restrictive pulmonary diseases, interstitial lung diseases or pulmonary hypertension. Assessment of patients on home oxygen therapy is usually done with arterial blood gas analysis.

Arterial blood gas sampling is invasive and can be painful. Cutaneous carbon dioxide is a non-invasive surrogate of $PaCO_2$. It is used both to estimate $PaCO_2$ and to determine trend changes.[59]

Long-term oxygen therapy is routinely used in patients with hypoxemia due to severe obstructive and restrictive pulmonary diseases, interstitial lung diseases, or pulmonary hypertension.[60-62] Oxygen therapy has been shown to improve survival and reduce hospitalization in patients with COPD and severe hypoxemia at rest.[63-65] Widely accepted indications for long-term oxygen therapy include a PaO_2 of –55 mm Hg (–7.3 kPa) while breathing room air.[60-62,66] In patients with complications such as polycythemia or evidence of pulmonary hypertension and/or episodes of right heart failure that reflect the systemic effects of chronic hypoxemia, continuous oxygen therapy should be prescribed even if the stable PaO_2 while breathing room air is 56 to 59 mm Hg (7.3 to 7.8 kPa).[60,61] The therapeutic goal is to maintain a pulse oximetric saturation (SpO_2) of –90% during rest, sleep, and exertion.[60-62,66] The guidelines for the assessment of home oxygen therapy vary depending on the country.[60-62] In Switzerland, oxygen titration consists of repeated arterial blood gas analyses, which includes the measurement of PaO_2 and $PaCO_2$ with and without supplemental oxygen. Arterial blood gas sampling is invasive and can be painful. Hence, there is a need for a noninvasive method. Since uncontrolled oxygen supplementation in hypercapnic patients can lead to the suppression of hypoxic respiratory drive, pulse oximetry alone is not adequate for the estimation of oxygen requirements, and the assessment of carbon dioxide (measured invasively or noninvasively) is also essential. Transcutaneous carbon dioxide tension ($PtcCO_2$) is a noninvasive surrogate of $PaCO_2$.[57] It is used both to estimate $PaCO_2$ and to determine trend changes. The measurement of $PtcCO_2$ is possible because carbon dioxide has high tissue solubility, diffuses through the skin, and can be detected by a sensor at the skin surface.[7] Combined cutaneous capnography and oximetry (SpO_2) is now possible with a single earlobe sensor.[5,7] This sensor is based on the Severinghaus principle, and $PtcCO_2$ is measured by placing a heated surface electrode on the skin. The application of heat to the skin surface increases blood flow into the arteriovenous anastomoses and the venous plexus, and capillary blood is arterialized. Patient factors that may influence $PtcCO_2$ values include hypoperfusion at the site of measurement, shock, edema, skin thickness, and vasoconstricting drugs.[57] Combining oximetry and cutaneous capnography may potentially reduce the need of arterial blood gas sampling.

Sleep Laboratory

The application of continuous $PcCO_2$ monitoring to overnight studies has been limited due to changing of the skin site of the probe after 4 hours and recalibrating to prevent thermal injuries to the skin. This is a time consuming procedure and the acquisition of the $PcCO_2$ values is delayed further by the equilibration time of up to 20 minutes. As discussed earlier, continuous $PcCO_2$ monitoring between 5 to 8 hours has been shown to be reliable in adults at a probe temperature of 43°.[67,68] However, the authors also reported that the time lag of $PcCO_2$ values was 5 ± 3 minutes and this was attributed to the lowering of the probe temperature to 43°C. The possibility to perform continuous eight hour $PcCO_2$ monitoring (with validation studies) would allow to study better the ventilation patterns during polysomnography and also be a tool for optimal titration of nocturnal noninvasive ventilation pressures in patients with chronic respiratory failure.

Lung Function Laboratory

This in another area where we feel that $PcCO_2$ monitoring has several potential applications (see Table 143.2). A suspected diagnosis of hyperventilation can be confirmed or excluded by the use of $PcCO_2$ monitoring.[69] $PcCO_2$ monitoring might be helpful for oxygen titration especially in patient with severe chronic obstructive pulmonary disease. Therefore, multiple arterial blood gas sampling can be avoided.

Cardiopulmonary Exercise Testing

Cutaneous estimations of PCO_2 and SPO_2 can be used in cardiopulmonary exercise testing, circumvening need for arterial canulation.[70]

Summary

Summary of applications and potential future use in clinical practice.

With evolution in technology $PcCO_2$ monitoring is now less cumbersome than before. Combined $PcCo_2$ and SpO_2 measurement has great potential to improve patient safety by better monitoring of ventilation during conscious sedation and general anesthesia, including postoperative surveillance. In clinical practice, instead of doing arterial blood gas repeatedly on patients receiving mechanical ventilation, non invasive ventilation and post-extubation, cutaneous capnography may offer a lesser invasive approach for decision making and patient management. In endoscopy room where pulse oximetry does not completely reflect the ventilation status, $PcCO_2$ combined with oximetry can help to detect hypoventilation. With more data coming from sleep laboratory, lung function laboratory and cardiopulmonary exercise testing the potential benefit of $PcCO_2$ measurement will help in oxygen titration, ventilation patterns during polysomnography and also be a tool for optimal titration of nocturnal non invasive ventilation pressures in patients.

Role of Ultrasonography in Critical Care Medicine

Pralay Sarkar, Seth J Koenig, Paul H Mayo

INTRODUCTION

Over the last two decades, ultrasonography has found a major application in the practice of critical care medicine. In the future, ultrasonography will have a major impact in advancing the quality of care in critically ill patients. The advantages of Critical Care Ultrasonography (CCUS) are evident; the intensivists personally perform the ultrasonography examination, so, they are in a position to immediately interpret the results in order to answer the clinical question under consideration. Thus, ultrasonography allows rapid diagnosis and therapeutic interventions at the bedside. Standard radiology or cardiology department based ultrasonography service inevitably introduces a time delay between the need for the examination, which is immediate and the performance of the examination, which is delayed, often by many hours. In addition, radiologists or cardiologists have minimal knowledge of the clinical situation. The time delay and clinical dissociation of the offline reader prevent their results from being integrated into the clinical plan quickly and efficiently as can be done by the intensivists. Performance of ultrasonography by intensivists also avoids the risk associated with transport of critically ill patients out of the Intensive Care Unit (ICU) for imaging studies.

By definition, the intensivist performs all aspects of the critical care ultrasonography examination at bedside like image acquisition, image interpretation and clinical application. The field of critical care ultrasonography has therefore been developed by critical care clinicians and is separate conceptually from the ultrasonography as practiced by the radiology and cardiology community. For this reason, the risks associated with the inexperienced intensivist ultrasonographer misinterpreting ultrasound results, misdiagnosing and mistreating their patients cannot be overstated.[1] Therein lies the importance of fellowship training programs incorporating a formal ultrasonography curriculum for their fellows including supervised, hands-on training.[1] Incorporation of ultrasonography into routine frontline critical care practice will require that professional societies develop high quality educational programs in order to ensure that attending level intensivists are fully trained in the discipline.

Healthcare quality has been usefully defined around six fundamental domains.[2] The usefulness and limitations of ultrasonography in improving care of critically ill patients can be described in reference to these quality care domains as summarized in Table 144.1.[3]

This chapter will review important applications of ultrasonography in critical care medicine. For more comprehensive review of the field, the reader is referred to standard texts (See reference).

TRAINING IN CRITICAL CARE ULTRASONOGRAPHY

The intensivist who seeks to develop competence in critical care ultrasonography needs to follow an organized approach to training. A key question that needs to be answered is what constitutes the subject matter of the field. With the knowledge of this, the learner has a roadmap to follow. The American College of Chest Physicians (ACCP) in partnership with La Société de Réanimation de Langue Française (SRLF) has written a consensus statement that defines competence in critical

TABLE 144.1: Benefits and limitations of ultrasound in impacting quality of care in critical care

Quality of Care Domain	*Definition*	*Advantages of US*	*Limitations of US*
Safety	Reducing/eliminating errors that happen during healthcare experience	1. Safe, noninvasive 2. Available 24/7 at bedside with immediate interpretations 3. Eliminates risks associated with moving patients off ICU monitoring for diagnostic tests 4. Improves safety for procedures	1. Expertise variable 2. Inaccurate interpretation by an inexperienced operator may lead to serious errors. 3. Potential of excess use because of easy availability, often at expense of meticulous physical examination 4. May fail to use, more difficult to obtain, but better diagnostic tests.
Effectiveness	Using well established, evidence-based principles, provider experience and patient values in achieving the desired care.	Guidelines for clear indications of ultrasound use in critical care are emerging	Requires adequate operator training/experience. Requires adequate acoustic window/imaging condition for satisfactory data gathering.
Efficiency	Using finite resources in the best possible way to optimize the value of resources	Being performed by the ICU physicians themselves, focused evaluation in a given clinical context can lead to efficient care without delay	Enough operator experience should be there for efficient data gathering and utilization of data in the care of the patient, being operated and interpreted by the clinician, lack of objectivity and confirmatory bias remain
Equity	Equal access to healthcare resources by all patients	Ultrasound is cheaper than many other imaging modalities	Costs of initial investment for equipments and personnel training mean that it will remain inaccessible in many ICUs in near future
Timeliness	Providing diagnostic and therapeutic services to patients in timely fashion when they need them	Critical care ultrasound is largely performed by intensivists themselves, being available readily when trained personnel are there.	24/7 intensivists proficient in using ultrasound may not be available.
Patient centeredness	Providing care and services to patients where they need it in a way that lead to a satisfactory healthcare experience	Use of a safe, fast modality reduces the burden on the related to unnecessary transport and pain. Immediate information can be communicated to the patient and family. Immediate implementation of actions based on results can improve patient satisfaction	Not available in all ICUs round the clock

care ultrasonography[4] (Table 144.2). This statement outlines in simple format the elements of the field that define competence.

Training in critical care ultrasonography requires mastery of the cognitive elements of the field; this is available in the standard textbooks and medical literature and in well designed e-learning format (http://www.iccuelearning.com). Image acquisition is the second mandatory component of competence and can only be learned by repeated practice, initially with normal subjects followed by practice on patients. Image acquisition is a key element of competence because the intensivist personally performs the ultrasonography examination at the bedside. Mastery of image acquisition requires knowledge of machine control, transducer manipulation and scanning protocol. It requires that the learner should be trained by a knowledgeable supervisor. There is also a major auto-didactic component to acquiring skill at image acquisition, so, the trainee should devote many hours of hands-on practice. The third component of training is for image interpretation. This requires review of

TABLE 144.2: ACCP Expert Consensus Statement on competence in critical care ultrasound[4]

Basic Principles

- Understanding of fundamental principles of ultrasound physics
- Knowledge of machine and transducer controls
- Knowledge of normal and abnormal ultrasound anatomy
- Knowledge of the pathophysiologic consequence of the imaged abnormality
- Knowledge of image interpretation, clinical applications, and specific limitations of ultrasonography.
- Ability to understand the goal directed nature of ultrasound examination in a critical care setting, in search of a specific clinical question.

Pleural Ultrasonography

- Identification of presence of pleural effusion as a relatively hypoechoic or echo-free space surrounded by typical anatomic boundaries like diaphragm, chest wall, ribs, normal/abnormal lung
- Identification of other important structures in the neighborhood like liver, spleen, kidney, heart, pericardium, spinal column, aorta, inferior vena cava
- Identification of characteristic dynamic findings of pleural fluid
- Characterization of fluid
- Identification of miscellaneous findings such as pleural-based masses or thickening
- Performance of semi quantitative assessment of fluid volume
- Recognition of specific limitations of ultrasonography to identify pleural fluid due to inadequate image acquisition conditions or nature of pleural fluid/other pleural pathology.

Lung Ultrasonography

- Identification and characterization of the normal aeration pattern
- Identification and characterization of consolidated lung with or without air bronchograms
- Identification and characterization of alveolar interstitial pattern
- Identification and characterization of air artifacts to rule out pneumothorax
- Identification and characterization of findings that rule in pneumothorax, e.g. presence of lung point (both by 2D imaging and M-mode).

Abdominal Ultrasonography

- Identification and characterization of intraperitoneal fluid by static and dynamic image characteristics. Qualitative assessment of intraperitoneal fluid volume
- Identification of all the relevant abdominal structures like abdominal wall, diaphragm, liver, gallbladder, spleen, kidney, bladder, bowel, uterus, spinal column, aorta, IVC
- Assessment of the urinary tract which includes identification of bladder, identification of urinary catheter, identification of abnormal bladder contents; differentiation of distended bladder from ascites
- Identification of both kidneys, presence or absence of hydronephrosis, measurement of kidney in longitudinal axis
- Identification of abdominal aorta, assessment of the aorta, identification of abdominal aortic aneurysm.

Vascular Ultrasonography: Guidance of Vascular Access

- Identification of relevant central and peripheral veins and arteries: internal jugular/carotid, subclavian vein/artery, axillary vein/artery, brachial vein/artery, radial artery, femoral vein/artery vein, peripheral veins such as basilic, cephalic, external jugular vein
- Differentiation of vein from artery based on anatomic position, compressibility, phasic changes during respiration
- Identification of adjacent nonvenous structures such as muscle, mass, lymph node
- Identification of normal anatomic variability in structure and position
- Identification of vascular thrombosis.

Vascular Ultrasonography: Diagnosis of Venous Thrombosis

- Identification of relevant veins and their associated artery: internal jugular, subclavian, axillary, brachial, basilic, common femoral, proximal saphenous, superficial femoral, popliteal
- Identification of venous thrombosis by visualization of endoluminal thrombus
- Knowledge of correct performance of compression study with identification of normal and abnormal results
- Identification of adjacent structures, e.g. lymph node, mass, hematoma, ruptured Baker cyst, etc.

both normal and abnormal images, not only for purposes of identification of disease, but also for integrating the knowledge into clinical management. Like image acquisition, image interpretation requires many hours of review of relevant images. It is not clear at the present time that how many scans must be performed or images reviewed to achieve competence. An international consensus group is working to develop guidelines for training and it is an area of active research. The ACCP-SRLF statement will be the foundation document for the development of training guidelines. Presently, there is no mechanism available in Europe, America or Asia for a formal certification process in critical care ultrasonography. This will be a future challenge.

TECHNICAL CONSIDERATIONS

In critical care ultrasonography, the intensivist is responsible for all aspects of image acquisition. This requires a knowledge of basic ultrasound physics, an understanding of common artifacts of ultrasound imaging and knowledge of machine function.

The Physics of Ultrasound

Sound is created when a moving/vibrating object creates alternate pressure or density changes in sequential layers of surrounding media. The media can be conceptualized to be comprised of columns/layers within each layer, the matter undergoes alternate compression and rarefaction or alternate high and low points of pressure change (Fig. 144.1). One layer, during the pressure change, transmits some energy to the next layer and thereby the sound propagates.

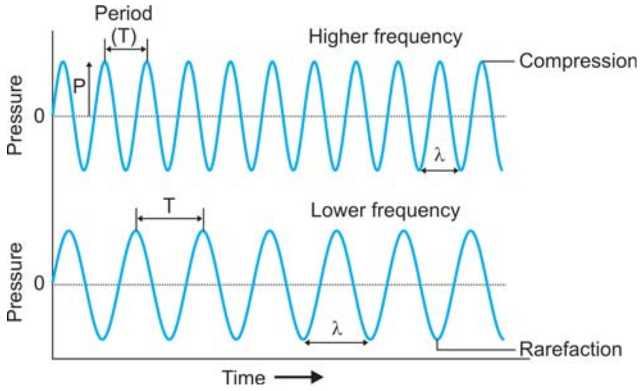

Fig. 144.1: Characteristics of sound. Sound propagation can be represented in a sinusoidal waveform. As sound propagates, each layer of medium undergoes compression and rarefaction and pressure changes. Note the inverse relationship between frequency and wavelength of sound. (*Source:* With permission from www.usra.ca)

Several parameters are described as follows which are used to define the properties of sound (Fig. 144.1):

Cycle and period: A cycle is one complete vibration of the medium with change of pressure/density of the medium from baseline to a high point through a low point back to the resting position. The time necessary for the sound wave to complete one cycle is known as its period (T). Period is measured in units of time, usually µsec.

Wavelength: The length of a single cycle measured in units of length is called a wavelength (λ). The wavelength of sound in a particular medium is inversely proportional to the frequency of the sound and is defined by the formula:

Wavelength = Speed of the sound in the medium/Frequency

The wavelength of diagnostic ultrasound is 0.1–0.6 mm.

Frequency (f): The number of cycles completed in one second is known as frequency. A standard measure of frequency is Hertz (Hz); one Hertz is one cycle per second (cps) (1 Hz = 1 cps). Ultrasound, by definition, is sound with frequency of more than 20 KHz (1 kHz = 1000 Hz). Typical frequencies used in diagnostic ultrasound range from 2–10 MHz (1 MHz = 1 million Hz). Most emitted and reflected sounds contain a lowest frequency, known as the fundamental frequency, and multiples of the fundamental frequency, known as harmonic frequencies or simply harmonics.

Amplitude: With the propagation of sound, the particles in the medium move from their resting position, leading to change in pressure and density. The particles come back to their resting positions, and pressure and density also return to the baseline. The difference between the peak and resting values of any of these parameters, pressure and density, is called the amplitude (P) of the sound. Amplitude is a reflection of the "loudness" and the energy of the sound. The amplitude of the sound is described on a logarithmic scale; the units of this scale are "bells". A decibel (dB) is 0.1 of bells.

Power: The amount of energy delivered per second is defined as power. Power = k x $(\text{amplitude})^2$ [k is the coefficient]. The unit of power is "watts".

Intensity: Intensity is the amount of energy delivered per second to the surface of the medium and is defined as power per unit area (expressed in the unit watts/cm^2). It is directly proportional to the power (amplitude) and inversely proportional to the area. Intensity of ultrasound determines the biological effects of ultrasound such as tissue heating. Diagnostic ultrasound typically uses an intensity of 0.001 to 100 watts/cm^2.

Speed: Propagation speed of sound in a particular medium is determined by the density of the medium. Speed of sound is 1540 m/s in soft tissue, 1450 m/s in fat, 300–1200 m/s in lungs and 2000–4000 m/s in bone.

Generation of Ultrasound and the Ultrasound Image

Generation of ultrasound is based on the "principle of piezoelectricity". Piezoelectricity is the ability of some natural and artificially made materials to generate an electrical potential when a mechanical stress is applied to them. The induction of a voltage across the material on application of mechanical stress is known as direct piezoelectric effect. The same materials also exhibit the reverse piezoelectric effect: the production of stress and/or strain when an electric field is applied. The piezoelectric material used in the ultrasound transducer is usually lead zirconate titanate (PZT) crystals.

An ultrasound probe contains multiple elements of a piezoelectric material. These elements act as acoustic transducers. Under an electric voltage, these elements undergo mechanical distortion. When the applied voltage is turned off, the crystals come back to their original shape. During this change of shape, some of the mechanical energy is converted into sound energy which is emitted by the transducer towards the target organ. Whenever the ultrasound waves encounter a surface or an interface with a different density, part of the sound wave is reflected back to the probe and is detected as an echo (see below). The energy of the reflected sound wave deforms the crystals. This generates an electrical current that the machine processes and displays as a pixel (Fig. 144.2). The stronger the reflection, the greater is the strength of the returning echo and the greater is the strength of the electrical current it generates. An ultrasound beam contains multiple wavelets, each one after reflection contributing a pixel in the image. Thus, multiple wavelets within an ultrasound beam, after reflection from multiple adjacent points within a target organ, create a collection of pixels, the image of the organ. Ultrasonography machines perform all the time calculations assuming that speed of travel of ultrasound waves in human tissues is 1540 meters/sec. The distance from the transducer of the object causing the echo is calculated from the time delay between generation of the ultrasound from the transducer and reception of the reflected sound. The longer the delay, the deeper the structure will be represented within the image.

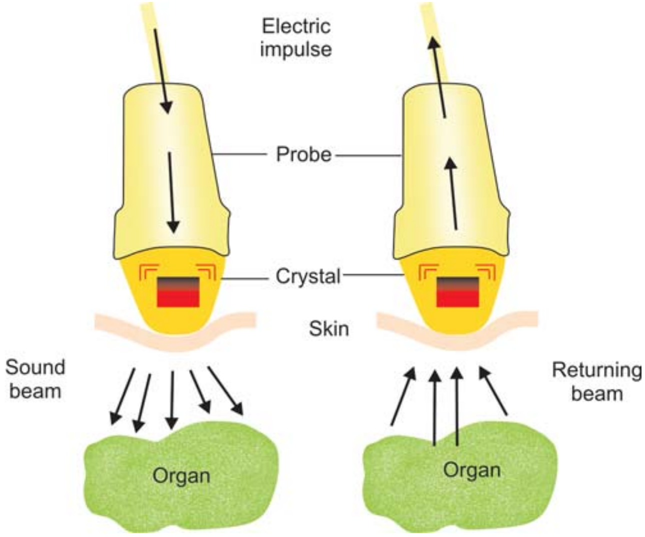

Fig. 144.2: Generation of ultrasound. Application of a voltage to PZT crystals lead to their mechanical distortion and generation of ultrasound waves. Reflected ultrasound waves deform the crystals leading to the generation of electrical impulse. (*Source:* With permission from www.usra.ca)

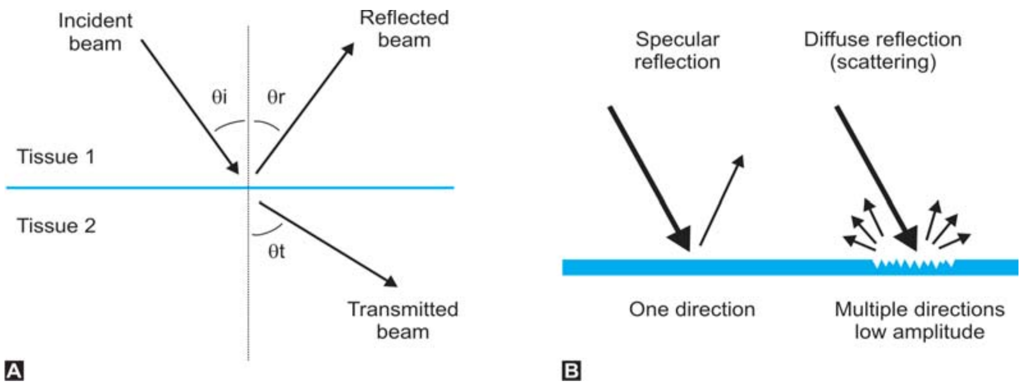
Interaction of Ultrasound with the Medium and at Interfaces

As ultrasound travels from its source through a medium (tissue), it undergoes progressive loss of energy (i.e. reduction in amplitude) and this process is known as attenuation. Ultrasound is absorbed by the medium causing attenuation and in the process generates heat. Attenuation depends on the frequency of ultrasound and the nature of the medium. In any given medium, the higher is the frequency of the ultrasound (i.e. shorter wavelength), the greater will be the attenuation.

At the interface between two mediums (or two different tissue layers), a part of the ultrasound beam undergoes reflection and the other part is transmitted forward (Fig. 144.3A). The reflected part of the ultrasound (echo) forms the basis of all diagnostic imaging. The amount of reflection at any interface depends on the difference in the acoustic impedance of the two media and the wavelength of the ultrasound. Most soft tissues have similar impedance typically at the boundary of two soft tissues (i.e. kidney/fat), only 1% of the ultrasound is reflected. On the other hand, ultrasound is intensely reflected at the surface of bones; as no ultrasound can penetrate the bone, no structure can be seen beyond a bony structure. Ultrasound also undergoes scattering (i.e. intense multidirectional reflection) in air (Fig. 144.3B). If air is interposed between the ultrasound beam and the target object, the energy in



Figs 144.3A and B: Interaction of ultrasound with the medium and at interfaces. (A) Shows refraction and reflection of ultrasound at the interface between two media. (B) Shows specular reflection and scattering. (*Source:* With permission from www.usra.ca)

the ultrasound beam is lost by scattering; the returned echo is minimal and a satisfactory image cannot be obtained.

Reflection is also determined by the wavelength of the ultrasound. The smaller is the wavelength, the smaller will be the size of object capable of reflecting it. If the boundary between two media is imagined as made up of multiple small reflectors, it follows that the finer details of the boundary can be seen if the wavelength of the ultrasound is smaller than the size of those small components of the boundary. In other words, resolution (i.e. ability to see two close-by objects separately) improves. Similarly, if two components of the boundary or two objects are separated by a distance greater than the wavelength of the emitted ultrasound, they are clearly seen as separate objects.

The intensivist ultrasonographer needs to have a clear understanding of the relationship between penetration, resolution and the frequency of ultrasound. Ultrasound waves of higher frequency (i.e. shorter wavelength) are reflected easily by smaller objects, thereby improving resolution. However, as more energy is reflected by superficial structures and through attenuation, the ability of higher frequency ultrasound to penetrate deeper structures is limited. Higher frequency ultrasound images superficial structures in greater detail but cannot penetrate to image deeper structures. Higher frequency ultrasound is therefore used for vascular studies and studies of superficial structures. Conversely, lower frequency ultrasound is used to image deeper structures although with a predictable loss of resolution (e.g. in abdominal ultrasonography).

Important Terminologies Related to Ultrasound

Attenuation

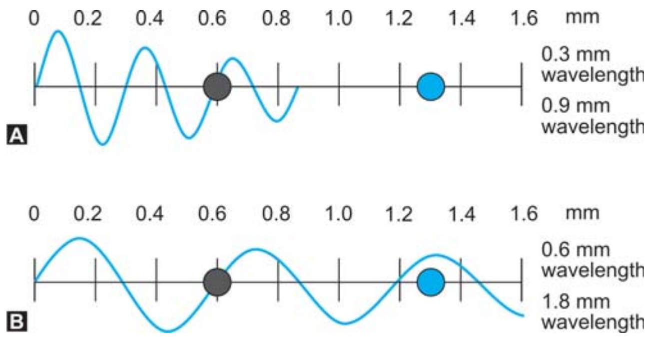
The progressive decline in amplitude or strength of ultrasound, as it passes deeper through the tissues, is known as attenuation. While attenuation is the result of absorption of sound energy as it passes through the tissue, reflection of ultrasound at each level also weakens the strength of the beam that penetrates further.

Echogenicity

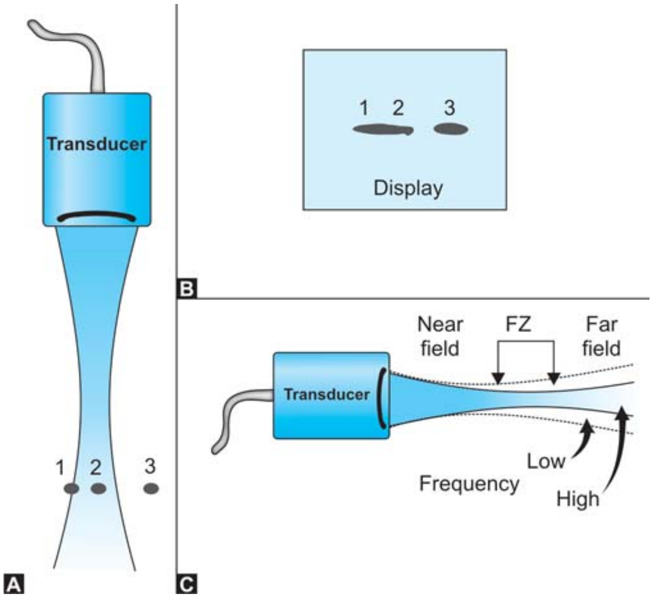
The term echogenicity refers to the brightness of an element in an ultrasound image. Echogenicity depends on the strength (amplitude) of the reflected ultrasound. A hypoechoic structure appears less echogenic than the surrounding anatomical structures. A hyperechoic structure appears more echogenic than the surrounding anatomical structures. An isoechoic structure has the same echogenicity as the surrounding anatomical structures. An anechoic structure has absent echogenicity and it appears black. Fluid filled structures are often anechoic. Some ultrasonographers use the liver as the reference standard to judge echogenicity for other structures.

Resolution

Resolution, specifically spatial resolution, refers to the ability of the machine to show two closely spaced objects as separate entities with distinct outline. Resolution determines the details of a structure. Axial resolution refers to the minimum distance between two objects placed along the axis of the beam, where the two structures are identified as separate. Axial resolution depends on the frequency of the ultrasound (Fig. 144.4). Lateral resolution is defined as the minimum distance between two objects placed along a line perpendicular to beam axis, where the two structures are identified as separate. Lateral resolution is largely dependent on the width of the ultrasound beam and may be improved to some extent by altering the focal zone of the transducer (Figs 144.5A to C). Line density contributes to lateral



Figs 144.4A and B: Axial resolution depends on pulse length. An ultrasound pulse commonly consists of 2 or 3 sound cycles of the same frequency. A higher frequency ultrasound has shorter cycle length and therefore provides better axial resolution. In Fig. 144.5 A, the axial resolution is sufficient to distinguish the 2 target objects as separate because the incident wave hits target # 1 (black) before hitting target # 2 (blue). In Figure 144.5B, both target # 1(black) and target # 2 (blue) are hit by the same wave and both target objects are seen as one. (*Source:* With permission from www.usra.ca)



Figs 144.5A to C: Lateral resolution depends on the ultrasound beam width, which in turn is inversely related to the ultrasound frequency. Lateral resolution is poor when the two structures lie at the same depth within the same beam width. Because the returning echoes overlap with each other side by side, the two structures (1 and 2 in figure) will appear as one on the display (A and B). Lateral resolution is best at the focal zone where the width of the beam is also narrowest (C). Keeping the target object at the focal zone helps to obtain the best resolution. (*Source:* With permission from www.usra.ca)

resolution, a factor that can be modified by a machine with sophisticated controls.

Artifacts

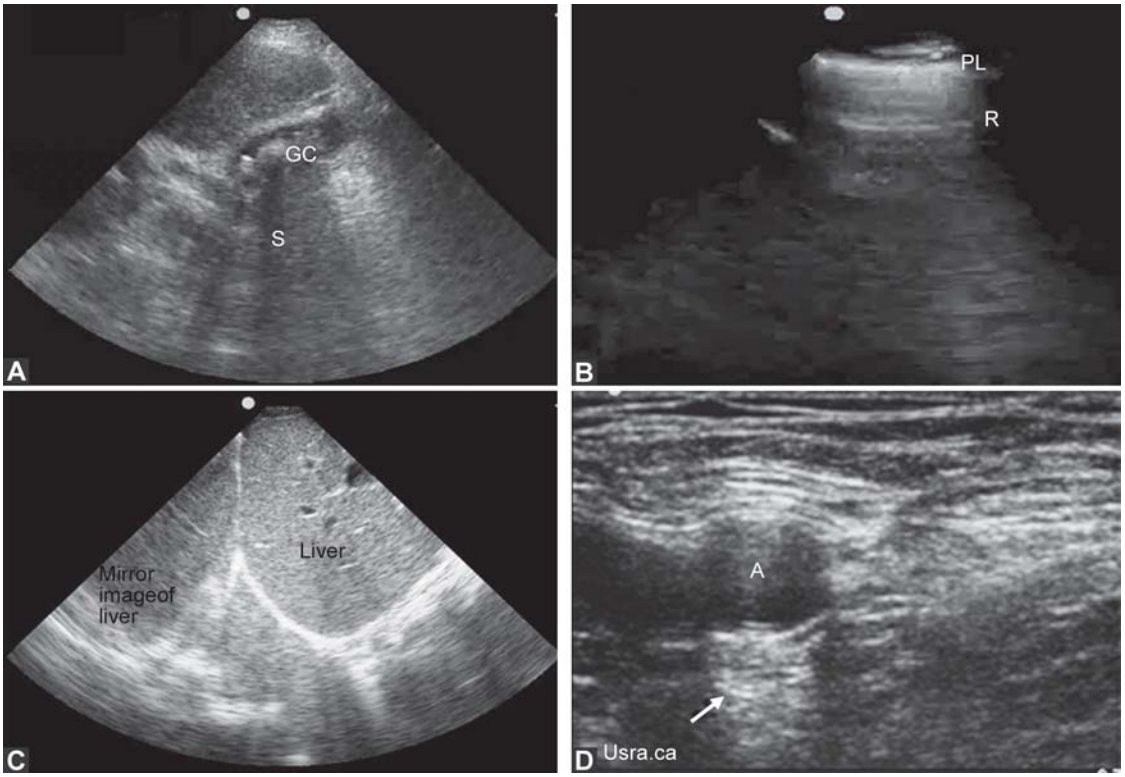
Artifacts are features of the image that do not originate from the object being imaged.[5] The intensivist ultrasonographer needs to be able to identify different types of artifacts in order to avoid errors related to their misinterpretation. Artifacts may arise because of equipment problems, patient related factors (e.g. obesity), unsatisfactory operator technique (e.g. due to inappropriate gain setting), movement of the target organ (e.g. due to translational respiratory artifacts) or because of sound-tissue interactions. This last category of artifacts (sound-tissue artifacts) results from the physical characteristics of ultrasound and the way it reacts with tissue. Common types of sound-tissue artifacts are discussed below.

Acoustic Shadow Artifact: This artifact occurs when a structure which is near, totally reflects the incident ultrasound beam and the ultrasound beam penetration is severely impeded. No structure beyond the reflector is visible, as the deep structures are shadowed by the reflector. Examples of acoustic shadow artifact include a gall bladder stone with a shadowing deep to it (Fig. 144.6A) or rib shadows.

Reverberation Artifact: This artifact occurs when the ultrasound beam is reflected back and forth between two surfaces. The depth of an image is calculated by the ultrasound machine by the time delay between sending the ultrasound beam and receiving the reflected echo. With each reflection in the closed space between two surfaces, part of the reflected beam escapes and reaches the transducer after a delay that is exact multiplicative of the time that the first reflection needed to reach the transducer. For each such reflection, the machine has no way to differentiate from the first reflection. Each reflection is therefore interpreted by the machine as an object that resembles the original reflective surface, at a depth that is multiplicative of the distance between the two reflective surfaces (Fig. 144.6B). Some of the important findings in lung ultrasound are based on the principle of reverberation artifacts.

Mirror Image Artifact: This artifact occurs if a reflector in the path of the beam has a curved structure (e.g. diaphragm) and reflects sound like a mirror (Fig. 144.6C).

Posterior Acoustic Enhancement Artifact: This artifact is typically seen as a hyperechoic area deep to a fluid-filled (anechoic) structure. The beam passes through the



Figs 144.6A to D: Common ultrasound imaging artifacts: (A) Gallbladder stone (GC) with acoustic shadow artifact (S). (B:)Reverberation artifact (R) from reverberation of ultrasound from pleural line (PL). In lung ultrasonography, these artifacts are known as A-lines. (C) Mirror image artifact. Strong reflection of ultrasound from a specular reflector like diaphragm creates a mirror image of liver. (D) Posterior acoustic enhancement artifact, appearing as a hyperechoic region (arrow) deep to a fluid filled structure (e.g. a vessel, **A** = artery). (*Source:* Right lower panel www.usra.ca with permission)

area of very low attenuation coefficient and enters an area deep to the structure with more energy than the ultrasound beam that has not passed through the fluid filled structure. As the beam enters an area of higher attenuation with more energy, there is much stronger reflection, making that area appear hyperechoic (Fig. 144.6D).

Different Ultrasound Modalities

Two-Dimensional (2-D) Imaging

Most critical care ultrasonography is performed with 2-D imaging technique, also known as B-mode ultrasonography. The most common transducer is either of a phased array or linear array design. The ultrasound beam is rapidly cycled across the transducer head, typically at 30 or more times per second. At this frame rate, the operator observes an uninterrupted pattern of organ motion on the 2-D image.

M-Mode (Motion Mode)

A M-mode image displays the movement of all structures against time along a single beam line (Fig. 144.7). The single beam line is displayed against a time axis. Each reflecting structure in the path of the beam is represented by a line; the undulation of the line along the Y-axis of the image reflects the movement of the structure while time is represented along the X-axis. If a structure in the path of the beam has no movement over time, it will be reflected as a straight line. M-mode is useful for measuring rapidly moving cardiac structures as the sampling frequency is much higher than the 2-D imaging, on the order of 1200 sampling cycles per second.

Doppler Imaging

Doppler is particularly useful for measurement of blood flow velocity. It has an extensive utility in advanced critical care echocardiography, but is seldom used in other aspects of critical care ultrasonography. The physics

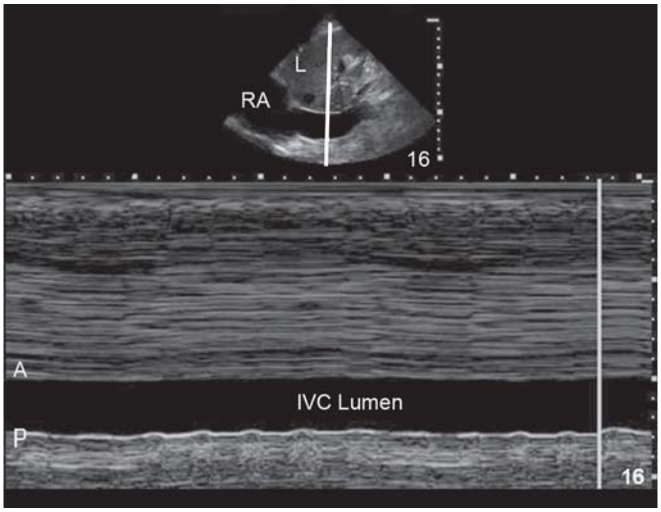


Fig. 144.7: M-mode examination of IVC. The upper panel of the figure shows the level (longitudinal section at right paramedian location) where the M-mode examination was performed. ***A*** represents anterior wall of IVC and ***P*** represents posterior wall of IVC. In this case, minimal respiratory variation of IVC lumen size is indicated by minimal undulation of the lines **A** and **P**. RA= Right atrium; L= Liver

and imaging strategy of Doppler ultrasonography is beyond the scope of this text. The reader is referred to definitive resources.[6]

Machine Controls

The intensivist ultrasonographer is responsible for all aspects of image acquisition. This requires knowledge of the machine controls (Fig. 144.8). Machines of different manufactures have control surfaces of radically different designs. It is not possible to describe here the details of the machine controls that are specific to a wide variety of machines. Some full capability ultrasonography machines have very complex controls that require a well aquainted ultrasonography technician for their proper operation. In general, portable machines are designed for the ease of operation and the control surfaces are relatively simple. A well designed portable machine with straight forward controls can be mastered easily by the intensivist. In a generic sense, the operator must be able to locate and learn to manipulate the following basic controls.

Depth: All modern ultrasonography machines of use in ICU allow for depth control. The operator can choose to examine superficial or deep structures by altering the depth of penetration of the ultrasound beam. As a general rule, the depth is set so, that the target structure is located at the middle of the screen.

Projection Indicator: All machines have an indicator on the screen that is referenced to a marker on the transducer. In any given ultrasound image, the structures which are on the side of the transducer marker are projected to the indicator side of the screen image. By international convention, abdominal, thoracic and vascular ultrasonography is performed with the screen image indicator, set to the left of the screen; whereas echocardiography is performed with the screen indicator on the right of the screen.

Gain: All modern ultrasound machines have a gain control. The gain control is adjusted to optimize the brightness of the image. The gain is a feature of image processing, that amplifies the returned echo. The effect of increasing gain is to increase the brightness of the image. The strength of the echo returning from deeper structures is often weak. Increasing the gain may improve image quality and the structures will be better seen on the screen. If the gain is set too high, nonspecific brightness will be seen throughout the image. Image quality will be degraded with the details and discriminations among different structures being lost. Brightness of different parts of the image can be adjusted individually to obtain an optimum image quality. This allows the ultrasonographer to adjust the gain individually for different objects at different depths from the surface. Echoes from the objects from near field are stronger and can be reduced in amplitude (gain reduced). The echoes from objects in far field (farther from the transducer) are weaker and can be increased in amplitude.

Zoom: Most machines allow the operator to magnify a specific part of the image for more detailed analysis.

Focus: Some machines have a focus control. This allows the operator to alter the width of the ultrasound beam at a specific point in the image, thereby improving lateral resolution in the area of interest. Other machines have automated this function such that the optimal focus point is at the center of the ultrasound image without need for machine adjustment.

Doppler Control: Control of Doppler ultrasound function requires knowledge of Doppler physics and is beyond the scope of this chapter.

Calipers and Freeze Function: Most ultrasound machines allow the operator to freeze the image, to replay the image in slow motion for review, and to make accurate measurements of distance and area from the frozen image.

Memory Function: Most modern ultrasound machines are designed with the ability to store both frozen images and video clips. Older generation machines may require a video or DVD recorder to be attached to the machine. Image and video capture is an essential component of good ultrasonography practice, as it permits documentation, off-line analysis, education and quality review.

THORACIC ULTRASONOGRAPHY

Thoracic ultrasonography that includes examination of lung and pleura is a key skill for the intensivist. It is easy to learn and has useful application at the bedside in day to day practice of critical care medicine. For example, it has utility for rapid diagnosis of patients with respiratory failure or for evaluation of acute dyspnea. Standard supine chest radiographs are difficult to interpret frequently due to nonspecific opacification pattern; whereas thoracic ultrasonography allows for accurate identification of pleural effusion, consolidation, atelectatic lung, alveolar interstitial syndrome and pneumothorax.[7] Ultrasonography has the potential to reduce the need for chest radiographs and chest computerized tomography with its high radiation exposure.[8,9]

Dr Daniel Lichtenstein is responsible for the development of lung ultrasonography. His original work in 1990s defined the field and has been validated by many other groups. Basic principles of thoracic ultrasonography have been defined by Lichtenstein:[10]

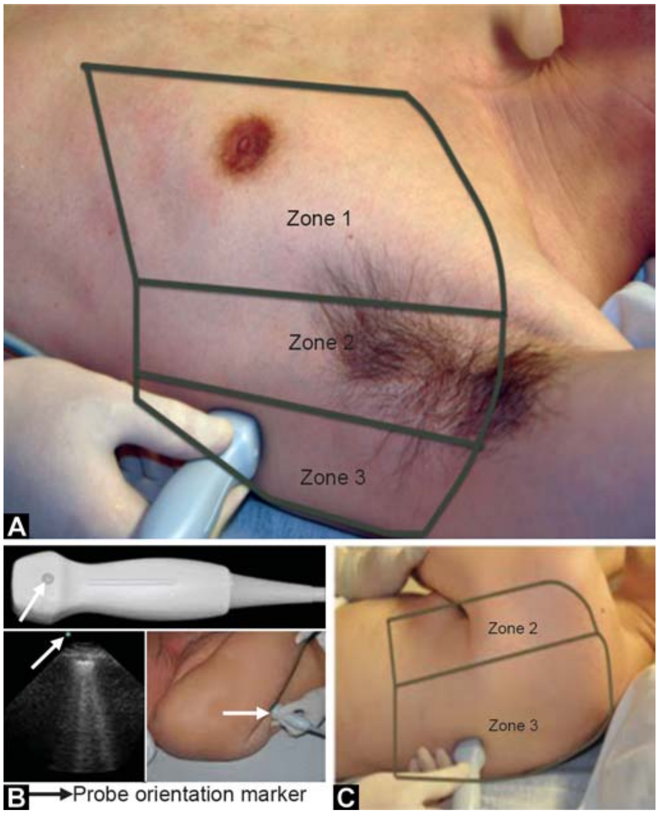
1. In the thorax, air and fluid have opposite gravitational dynamics, so, by inference, in the supine patient, pleural effusion will be seen posteriorly and pneumothorax will be seen anteriorly.
2. The lung is the most voluminous organ.
3. All lung signs arise at the level of the pleural line.
4. Lung ultrasonography is based on the analysis of artifacts.
5. Lung patterns are dynamic; serial examinations are valuable.
6. Most acute lung disorders abut the lung surface.

Equipment

Any ultrasound machine that is capable of abdominal or cardiac imaging can be used for thoracic ultrasonography. Most general ultrasonography is performed with transducers with the frequency of 3.5–5 MHz. A probe of this frequency and of convex-sector design can be conveniently used for longitudinal scanning through the intercostal spaces. Transducers of 3.5–5.0 MHz frequency range do not have sufficient resolution for a detailed analysis of pleural surface pathology. However, they offer better penetration so that deeper structures can be visualized. High frequency probes (7.5–10 MHz), designed for vascular examination, can be used for detailed pleural examination. These transducers allow excellent resolution of the pleural surface, but at the expense of limited penetration and visibility of deeper structures. Most standard ultrasound machines are adequate for thoracic ultrasonography, however some modern handheld units may lack adequate near-field resolution. When there is a pleural effusion, the inside of the chest wall may not be clearly visualized; this might lead to error in estimating the depth of needle penetration when performing thoracentesis. Some recent generation ultrasonography machines use extensive image processing for image smoothing. This may mask standard lung ultrasound findings such as lung sliding.

Examination Protocol

Lung ultrasonography in the critically ill patient is generally performed with the patient in supine position. It is useful to follow an organized protocol that divides the chest into anterior and lateral compartments (zones) (Fig. 144.9A). The former is the area between the sternum and the anterior axillary line, and the latter is defined as the area between the anterior and posterior axillary lines. With the transducer held perpendicular to the skin surface in a longitudinal scanning axis (Fig. 144.9B), the clinician examines the underlying pleural surface and lung through the rib interspaces. By moving the transducer over adjacent interspaces, the examiner can lay down a series of scan lines and develop a three-dimensional model of the thorax



Figs 144.9A to C: Technique of thoracic ultrasonography: (A) The lung can be divided into compartments for imaging. (B) Probe is placed longitudinally across the intercostals space with the orientation mark pointing upwards. (C) Probe placement in a supine patient to look for posterior effusion. (*Courtesy:* Dr Pierre Kory, Attending Physician, Department of Pulmonary and Critical Care Medicine, Beth Israel Medical Center, New York, USA and Assistant Professor of Medicine, Albert Einstein College of Medicine, Bronx, NY, USA)

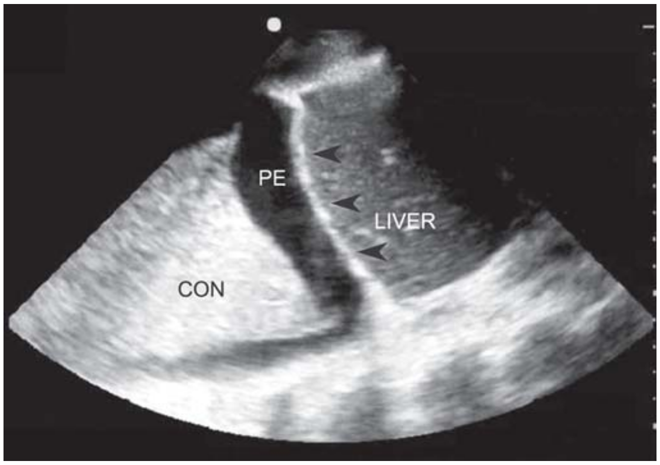


Fig. 144.10: In the longitudinal scanning axis, diaphragm appears as a bright curvilinear structure (arrowheads). Also seen in the image are liver, consolidated lung (CON) and small amount of pleural effusion (PE). The dense area of airless consolidated lung appears to have the same echodensity as liver, known as sonographic hepatization (see text).

by using a multiple tomographic plane approach. The posterior compartment, which lies between the posterior axillary line and the spine, cannot be imaged with the patient in the supine position. If there is a requirement to examine the posterior compartment, the patient can be rolled into a lateral decubitus position, alternatively, the transducer can be pressed into the mattress and angled towards the central body mass to obtain a partial view of the posterior structures (Fig. 144.9C). The probe should always be orientated to the marker on the probe points cephalad (Fig. 144.9), the machine should be set to project the screen marker to the left. Maintaining this rule in probe position and machine set-up helps the operator to remain orientated to the anatomic axis of scanning, as the cephalad structures of the image are always projected to the left of the screen.[11] The gain and depth setting should be optimized to achieve adequate magnification, resolution and brightness of the structures being examined. For example, for examining the pleural surface, the depth setting should be adjusted for near field examination. As lung ultrasonography is often performed to address a specific question, complete scanning of all lung zones may not always be required. Supine examination of the anterior and lateral chest wall can answer many clinically important questions. Examination of the anterior chest wall rapidly rules out pneumothorax and interstitial syndrome. Examination of the lateral chest wall is useful for the identification of free flowing pleural effusion and alveolar consolidation. Small pleural effusion and posterior consolidation can be detected by examining the posterior compartment.[11]

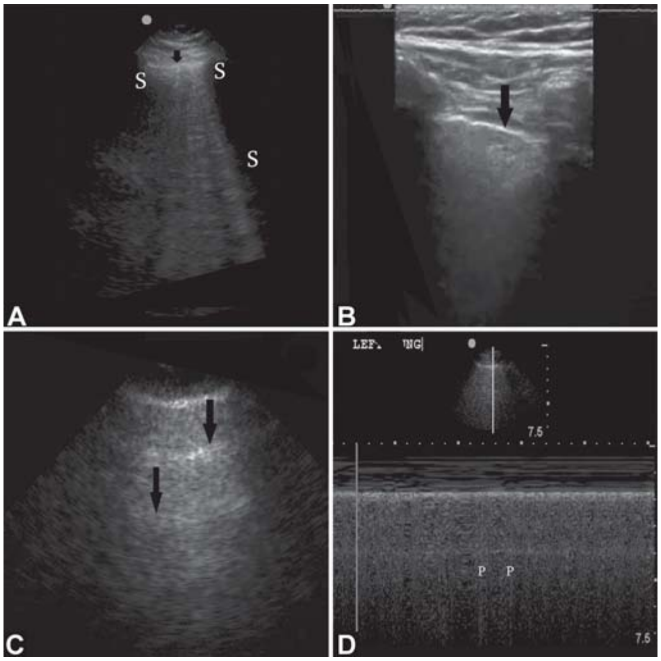
As standard protocol, the clinician should routinely visualize both the hemidiaphragms. In longitudinal scanning axis, the diaphragm appears as a bright curvilinear structure (Fig. 144.10) that moves in synchrony with respiration.

As an organizing principle, the large difference in acoustic impedance of ultrasound between air and tissue leads to intense reflection at any air-tissue interface. When parenchymal air is replaced by fluid or an infiltrative process, depending on the ratio of air to fluid, ultrasound findings progress from normal aeration pattern to alveolar/interstitial edema pattern to tissue density pattern.

Normal Findings

In a longitudinal scan through an intercostal space, the rib shadows are seen on both the sides of the image and serve as a basic landmark (Fig. 144.11A). Related to the major difference in the acoustic impedance between the chest wall and underlying air filled lung tissue, the ultrasound beam is strongly reflected from the surface of the lung. This point of reflection of ultrasound from the lung surface corresponds to the pleural surface. It appears as a bright, highly echogenic line between two adjacent ribs, approximately 0.5 cm below the periosteal origin of the rib shadow (Figs 144.11A and B). The normal pleura is 0.2–0.4 mm thick.[12] A 3.5–5.0 MHz probe does not allow sufficient resolution to visualize the parietal and visceral pleural surfaces separately so, that the pleural line represents a single summation interface. Aerated lung is not seen as an anatomically distinct entity because of strong reflection of the ultrasound beam at the pleural interface. However, aerated lung has a distinctive ultrasound pattern that results from reverberation artifact. Aerated lung is characterized by the presence of "A" lines which are horizontally orientated curvilinear hyperechoic lines, observed deeper to and parallel to the pleural line (Fig. 144.11 C). "A" lines may occur in single or multiple numbers and result from the reverberation of the ultrasound beam between the pleural surface and skin. If there is more than one A line in the ultrasound image, the distance between A lines will be a multiplicative of the distance between the pleural surface and the skin. Several A lines are often visible. The actual number of A lines has no significance as long as there is at least one.[13] A lines are strongly correlated with a normal aeration pattern on chest CT scan at the site of the transducer application to the chest wall.[7] Examination of the pleural interface is characterized by two dynamic findings: Lung sliding and lung pulse.

Lung Sliding: Lung sliding occurs due to the movement of the visceral pleura against parietal pleura in phase with respiration. Lung sliding appears as "twinkling" at the level of the pleural line, in rhythm with respiration.[13] An M-mode examination of the pleural line reveals a pattern known as the "sea shore" pattern and allows the examiner to document the presence of lung sliding with a single frozen image that can be easily printed out for documentation (Fig. 144.11D). Lung sliding is minimal at the apex and maximal at the lung bases. The presence of lung sliding indicates apposition of parietal and visceral pleural surfaces at the site of transducer placement. The presence of lung sliding rules out pneumothorax at the site of transducer placement on the chest wall. The examiner may quickly examine multiple interspaces over the anterior lung zones, thereby excluding pneumothorax with a high level of certainty.



Figs 144.11A to D: Normal findings in lung ultrasonography. (A) In longitudinal scanning through an intercostals space, the rib shadows (S) serve as the basic landmark. Pleura is seen as a bright echogenic line (arrow); (B) A high frequency probe (7.5 MHz in this image) shows the pleural line (arrow) in greater resolution; (C) A-lines (arrows) are generated by reverberation of ultrasound, a normal finding; (D) M-mode record lung sliding generates "sea-shore" pattern. Lung pulse (P) is also shown in the image

Lung Pulse: Lung pulse occurs due to the movement of the visceral pleura against parietal pleura in phase with cardiac contractions.[14] Lung pulse is best seen at pleural surfaces adjacent to the heart, but may be observed over the right chest as well. Lung pulse can be recorded with M-mode for purposes of easy documentation (Fig. 144.11D). The presence of lung pulse indicates apposition of the parietal and the visceral pleural surfaces at the site of transducer placement. The presence of lung pulse rules out the presence of pneumothorax at the site of transducer placement on the chest wall. The examiner may quickly examine multiple interspaces over the anterior lung zones, thereby excluding pneumothorax with a high level of certainty.

Abnormal Findings in Thoracic Ultrasound

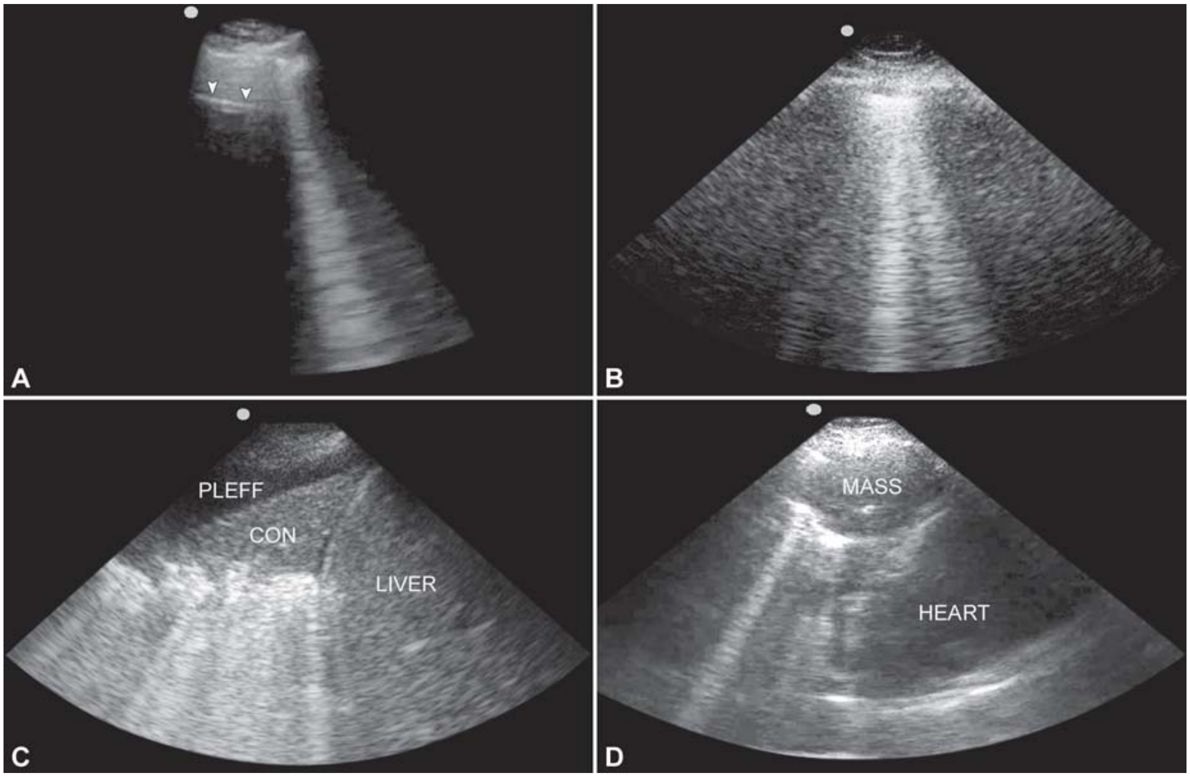
B Line(s)

B line(s) are an important finding of lung ultrasonography and often reflect the presence of pulmonary pathology. They have characteristic features which are as follows[13] (Figs 144.12A to D):

1. They are vertical in orientation.
2. They rise from the pleural line and move with the movement of the pleural line (in synchrony with lung sliding and lung pulse).
3. They spread to the bottom edge of the image.
4. They efface A lines at the point of intersection.
5. They are narrow at their point of origin at the pleural surface and spread out as they approach the edge of the image.

It is very important that the clinician ensures whether these criteria are fulfilled for definitive identification of B lines. B lines may reflect significant lung abnormality and can be mistaken for mimickers (Z line and I line).[13] The location and number of B lines determine their significance. A few B lines are often found in the lower lateral intercostal spaces in normal subjects.[15-17] Multiple B lines in the nondependent areas of lungs are usually of pathological significance, particularly if they appear as multiple comet tail artifacts. Multiple B lines evoke a pattern similar to a rocket at lift-off and the term "lung rockets" have been used to describe the pattern (Fig. 144.12 B). A pattern that is definitively pathologic occurs when at least three B lines are detected in a single scanning position over the anterior chest (Fig. 144.12 B).[16,17]

B lines or comet tail artifacts result from successive reverberation at the interface between air and pathologically thickened interlobular septa, at the lung visceral pleural interface.[16] This occurs most frequently when interlobular septae are distended with fluid or other infiltrative or inflammatory process. These include interstitial lung disease, e.g. idiopathic pulmonary fibrosis or sarcoidosis,[18] acute cardiogenic pulmonary edema, lung contusion, acute lung injury and acute respiratory distress syndrome,



Figs 144.12A to D: A. Line(s) arises from the pleural line and effaces A-line (arrowheads) at the intersection. B. Three or more B-lines in a single longitudinal scan plane is considered pathological. C. Shows multiple B lines (lung rocket) arising from the margin of an area of consolidation (CON). A small pleural effusion (PLEFF) is also seen. D. Shows a single B-line arising from the margin of subpleural lung mass. Of note, the lung mass provided an acoustic window to visualize the heart in this scan plane. Consolidated lung can also provide a suitable acoustic window to visualize a deeper intrathoracic structure

lymphangitic carcinomatosis and early/resolving lung consolidation.[15,16,19,20] B lines, when focal in location, suggest a localized process such as pneumonia. The presence of diffuse B lines suggests a generalized process such as cardiogenic pulmonary edema. Comet-tail artifacts have been associated with alveolar-interstitial shadows seen on chest radiograph and they can be considered equivalent to Kerley B lines seen on a plain radiograph. Lichtenstein et al. demonstrated tomodensitometric correlations of the thickened subpleural interlobular septa as well as ground-glass areas, two lesions present in acute pulmonary edema, with the presence of the comet-tail artifact.[16] Lichtenstein et al. have compared chest Computed Tomography (CT) findings with ultrasound and found 95% accuracy of ultrasonography in the diagnosis of alveolar-interstitial syndrome in comparison to CT scan.[7]

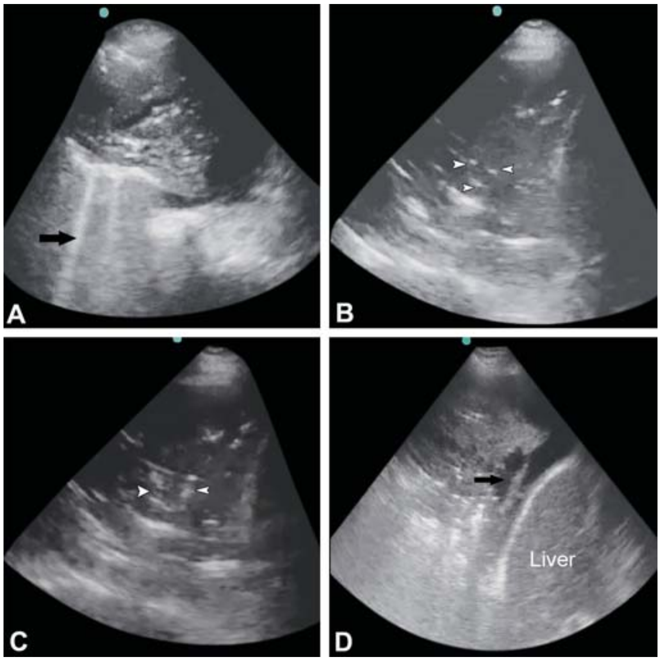
Acute cardiogenic pulmonary edema results in B lines. An elevation of left-sided cardiac pressures causes distension of interlobular septa in the nondependent lung zones. This distension of interlobular septa causes multiple B lines or comet tail artifacts in the nondependent lung zones. The findings of multiple B lines are therefore sensitive, but nonspecific means of detecting cardiogenic, i.e. hydrostatic edema. The presence of A lines in the nondependent lung zones is strong evidence that left-sided cardiac pressures are not elevated. Lichtenstein et al. have demonstrated that the presence of A lines in the anterior lung zones with the patient in the supine position indicates that the pulmonary artery occlusion pressure (PAOP) is always ≤18 mm Hg and usually ≤13 mm Hg.[21] Presence of A lines therefore excludes cardiogenic pulmonary edema as the cause for respiratory dysfunction. This fact has important clinical application as will be discussed later.

Alveolar Consolidation

Alveolar consolidation can be diagnosed by thoracic ultrasonography. Consolidated lung has tissue density without change in dimension with respiration. It has similar echodensity as liver; hence the term sonographic hepatization of lung has been used for descriptive purposes (Fig. 144.13A and D). The border between the tissue density of alveolar consolidation and aerated lung may be shredded or irregular and may exhibit B lines or comet tail artifact (Fig. 144.13A). Punctate echogenic foci may be visible within an area of alveolar consolidation. These represent air-filled bronchi and are termed as "sonographic air bronchogram".[22] Depending on the plane of scanning, they may appear as nonpulsatile, linear echoes converging towards the root of the lung or scattered echoes of variable lengths (Fig. 144.13A). Posterior reverberation artifacts or acoustic shadowing may also be produced by echoes related to large proximal bronchi.[23] The sonographic air bronchogram may be mobile and may exhibit movement that is independent of the surrounding movement of the lung related to respiratory cycle (Fig. 144.13B and C). The mobile air bronchogram (also known as dynamic air bronchogram) indicates that the bronchus supplying that area of alveolar consolidation is patent and not blocked by endobronchial pathology. In some cases, multiple, branching, nonpulsatile, anechoic, tubular structures can be seen within the area of consolidation representing fluid-filled bronchi; these are known as sonographic "fluid bronchogram".[24] Alternatively, they may represent pulmonary vascular structures, the distinction between the two may be made by color Doppler. Sonographic alveolar consolidation can be observed only if the process abuts the pleura allowing ultrasound to penetrate through the abnormality should the process be deep within the lung, it cannot be visualized through created lung due to the ultrasound blocking characteristics of air. In the majority of cases, alveolar consolidation abuts the pleura, making it easily accessible to ultrasound analysis.[25] Where a pleural effusion is present, it provides an acoustic window to visualize the underlying consolidation. Likewise, the presence of consolidation provides an acoustic window to visualize underlying structures that will not normally be visible such as heart or great vessels.

The finding of sonographic alveolar consolidation pattern is descriptive and does not imply a specific diagnosis such as pneumonia. Similar to plain radiography and CT scan, a sonographic consolidation pattern may result from a wide variety of pathological processes. Any disease process that results in airless alveolar structures can give rise to sonographic consolidation pattern like atelectasis (compressive or resorptive), infiltrative processes (tumor, purulent material as in pneumonia), severe pulmonary edema with flooding of alveoli, etc.

Alveolar consolidation can be accurately diagnosed by ultrasonography. In a study of critically ill patients, ultrasonography was found to have a sensitivity of 90% and specificity of 98% with high interobserver concordance for the diagnosis of alveolar consolidation using CT scan as the gold standard.[25] Alveolar consolidation may be localized to any part of lung and its identification requires clinical correlation. In a patient present with fever, cough, purulent sputum and dyspnea,



Figs 144.13A to D: Alveolar consolidation. A. An area of consolidation with sonographic air bronchogram (bright echogenic spots within the area of consolidation). Also seen are B lines (arrow) arising from the margin of the consolidation; B. Dynamic air bronchogram. During expiration, within the area of consolidation, air bronchogram appears as punctuate bright spots (arrowheads); C. During inspiration, the echogenic spots expand centrifugally towards the pleural surface into branching, echogenic structures (arrowheads) and represent air movement in the bronchi within the area of consolidation; D. Microabscesses within an area of consolidation (arrow) in a case of necrotizing pneumonia

demonstration of an area of consolidation suggests a diagnosis of pneumonia. In patients with necrotizing pneumonia, ultrasound is sensitive in detecting microabscesses (Fig. 144.13D); in complicated cases, it can be used for needle-aspiration guidance in order to obtain etiologic diagnosis with minor and infrequent complications.[22] Ultrasonography has been used to follow response to treatment of both community acquired pneumonia (CAP) and ventilator associated pneumonia (VAP). A decrease in size/number or disappearance of lesions indicates improvement in CAP.[26] In a recent study on VAP, gradual re-aeration of consolidated areas in response to antibiotic treatment was reflected by a continuum of changing ultrasound patterns. Significant correlations between CT and ultrasonography with higher accuracy than chest radiography have been shown in predicting lung re-aeration in this study.[20]

Areas of sonographic alveolar consolidation may be observed in cases of pulmonary embolism. In patients with clinical suspicion of pulmonary embolism, the diagnosis is supported by the sonographic finding of one or more triangular/rounded/wedge shaped areas of consolidation (consistent with pulmonary infarcts) with or without localized/basal pleural effusion.[27-29] The area of consolidation may show a central hyperechoic reflex corresponding to a bronchiole within the area of consolidation. Fresh reperfusion infarcts are homogenous and hypoechoic; older infarcts are less homogenous and well demarcated. Two or more triangular or rounded pleural-based sonographic ultrasound consolidations have been shown to have high specificity for the diagnosis of pulmonary embolism in patients with high pretest probability.[30]

The presence of dynamic air bronchogram is useful in differentiating pneumonia from postobstructive resorptive atelectasis. A pleural effusion commonly causes compressive atelectasis of the adjacent lung that will then have sonographic alveolar consolidation pattern as it is airless. In this case of compressive atelectasis, the bright echoes, representing air bronchogram, appear crowded towards the root of the lung.[23] Dynamic air bronchogram has been described as a helpful feature in differentiating pneumonia from post obstructive (resorptive) atelectasis[31] (Figs 144.13B and C). When present, it is considered good evidence against resorptive atelectasis. Lung sliding also suggests absence of resorptive atelectasis.[14]

Pleural Effusion

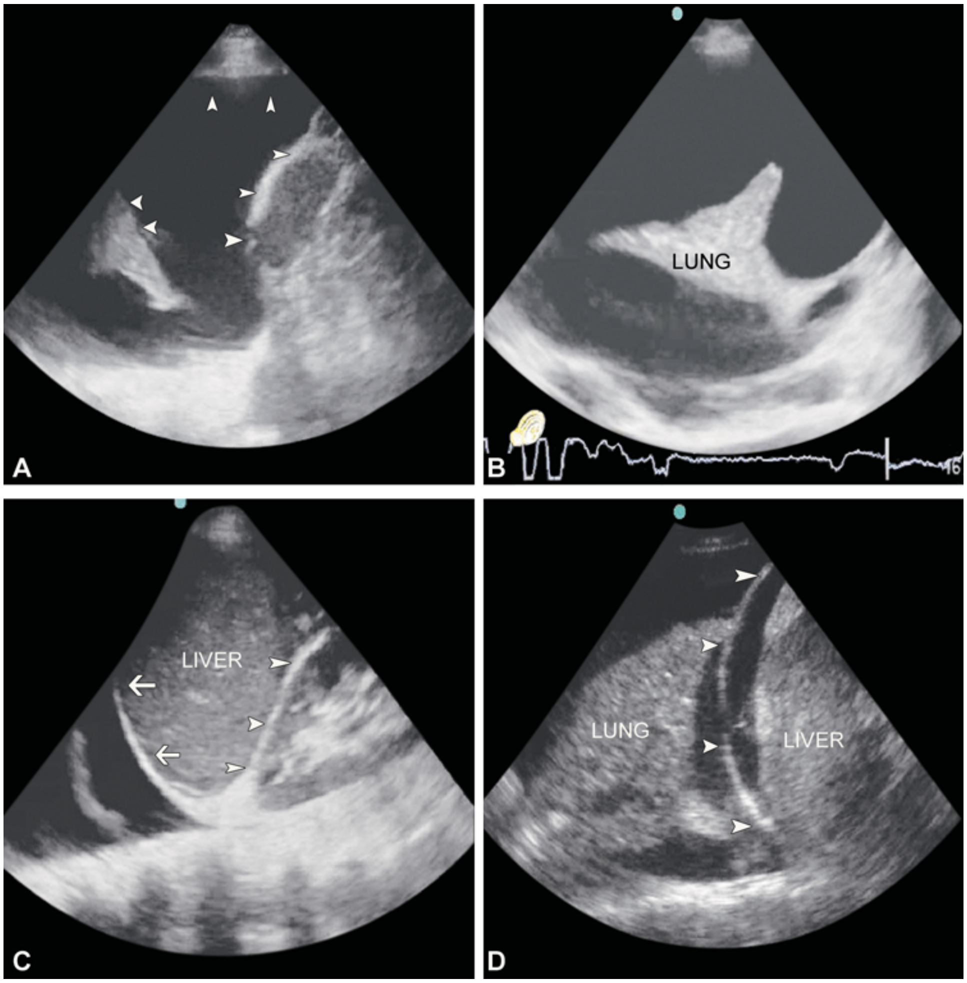
Ultrasonography is useful in the identification of pleural effusion. When the ultrasound detection of pleural effusion has been compared to chest CT scan or clinical confirmation by aspiration of fluid, its sensitivity and specificity of more than 90% has been recorded.[7,32] Ultrasonography is the imaging modality of choice in diagnosing pleural effusion in a supine critically ill patient.

The three cardinal features of ultrasonographic identification of pleural effusion are as follows:[11]

1. Presence of a relatively echo-free space
2. Typical anatomic boundaries that surround this space: the chest wall, the diaphragm and the visceral pleural surface of the lung (Fig. 144.14A)
3. Typical dynamic findings like movement of compressed lung during respiration

Pleural fluid, depending on its composition, may be anechoic or hypoechoic. A simple transudate may appear black (Fig. 144.14B) whereas a complicated pleural effusion may be more echoic (Fig. 144.15A).

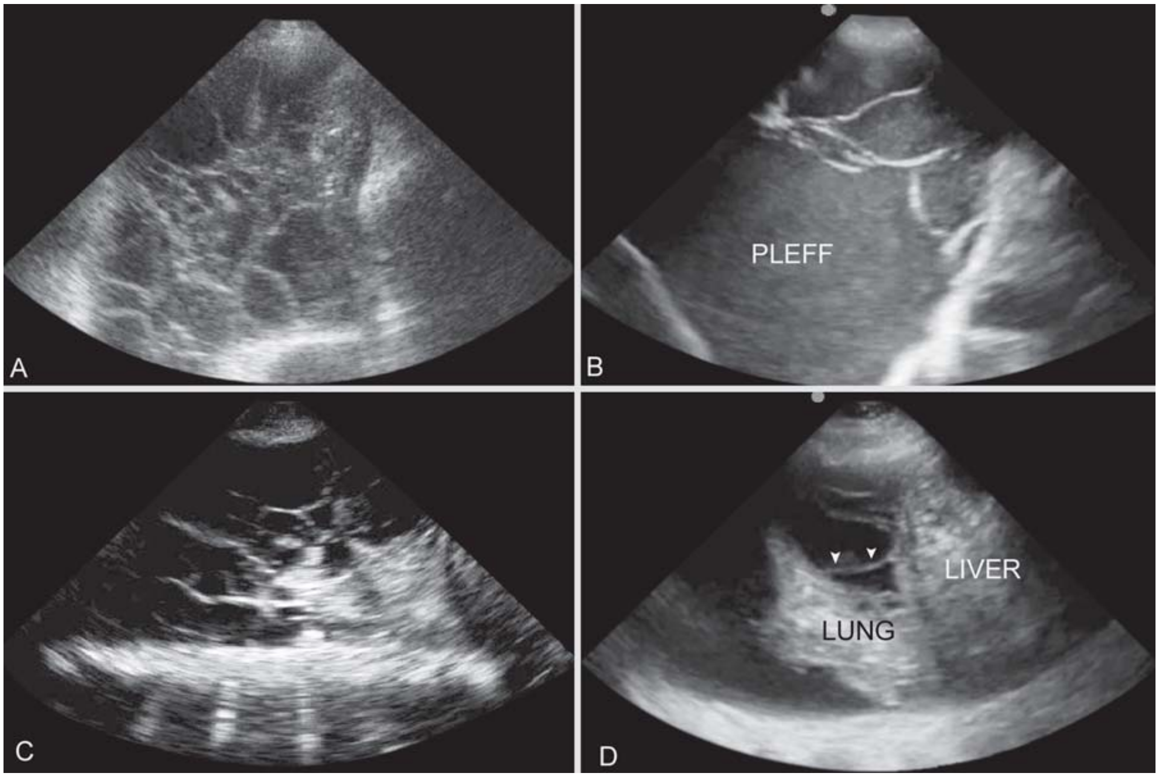
The typical anatomic boundaries are the inside of chest wall, the diaphragm and the visceral pleural surface of the lung. The inside of the chest wall may be difficult



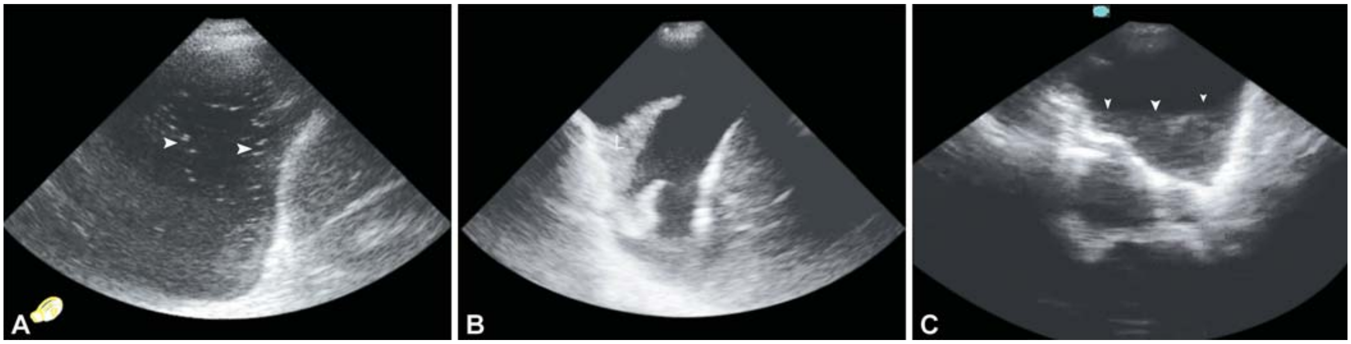
Figs 144.14A to D: Pleural effusion. A. Pleural effusion is identified by the typical anatomical boundaries (arrows): chest wall (above), diaphragm (right) and visceral pleural surface (left); B. Large pleural effusion. A typical transudative effusion is completely anechoic; C. Identifying the diaphragm (arrows) and liver/spleen below the diaphragm is critically important. The hepatorenal recess (arrowheads) may be erroneously identified as diaphragm and the liver as a complex pleural effusion, by an inexperienced operator. An attempted thoracentesis, in such a case, will lead to liver injury. D. Small pleural effusion. The patient also has ascites, seen as hypoechoic area below the diaphragm (arrowheads). Compressed lung shows an alveolar consolidation pattern

to visualize if there is near field clutter artifact. Its identification is important in order to estimate the depth of needle penetration needed to enter the pleural space. The diaphragm is identified as a curvilinear hyperechoic structure that moves with respiratory cycle. The liver or spleen is identified below the diaphragm (Fig. 144.14C). The visceral pleural surface of the lung demarcates the lung adjacent to the pleural effusion. The lung that is adjacent to a pleural effusion will have features of ultrasonographic alveolar consolidation pattern due to compressive atelectasis (Fig. 144.14D).

The dynamic findings characteristic of pleural effusion include lung flapping or jelly fish sign (Figs 144.16A to C) which is the undulating movement of compressed lung within the pleural effusion. A "curtain sign" occurs when aerated lung enters the scanning field during respiratory cycle and obscures visualization of the effusion. Cellular components within an effusion may have respirophasic or cardiophasic movement known as plankton sign (Figs 144.16A to C). Complex effusion may have undulating septations or fronds (Fig. 144.15D). M-mode ultrasound examination of the visceral pleural surface at the interface of the effusion often shows a "sinusoidal pattern", reflecting movement of the pleural surface within the fluid-filled space (Fig. 144.17).



Figs 144.15A to D: Complex pleural effusion. A. Echogenicity within the pleural fluid indicates complex pleural effusion. Also note the developing septations and loculations; B. Echogenic pleural fluid (PLEFF) in a case of hemothorax; C. Complex pleural effusion with multiple loculi; D. Septations (arrowheads) within a pleural fluid collection



Figs 144.16A to C: Other signs in pleural effusion. A. Complex pleural effusion within multiple echogenic foci (arrowheads). In real-time scanning, slow swirling motion of this echogenic material is known as 'plankton sign'; B. In real time scanning, the compressed lung shows an undulating movement, known as lung flapping or jellyfish sign; C. Hematocrit sign: In a richly cellular effusion, the cellular components can sediment forming a bilayer effect (arrowheads)

Free flowing fluid within the pleural cavity assumes a dependent position within the thorax due to gravitational forces. A loculated pleural effusion may be located in nondependent areas of the thorax. In supine patients, a moderate to large pleural effusion can generally be identified by scanning in the mid or posterior axillary line. Small pleural effusion may be difficult to identify due to a posterior location. The operator may need to press the transducer on the mattress and angle the ultrasound beam towards the central body mass. Alternatively, the patient needs to be placed in lateral decubitus position to scan the posterior areas.

Estimation of Pleural Fluid Volume (PEV): Several methods have been described for accurate estimation of pleural fluid volume based on ultrasonography

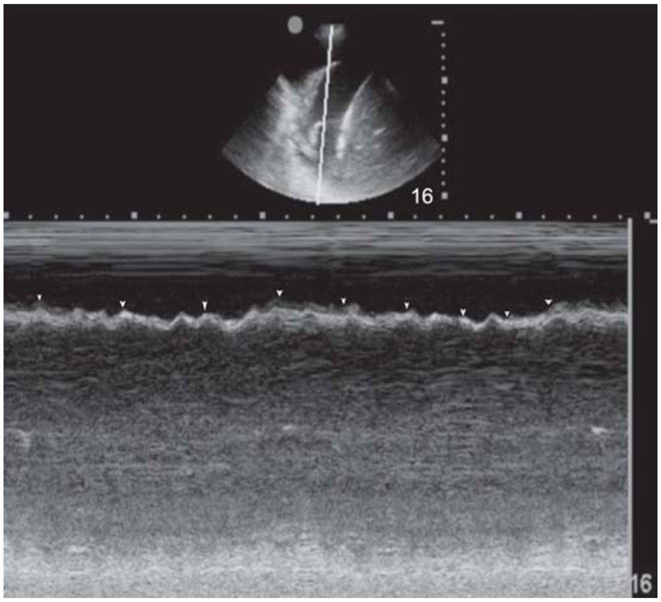


Fig. 144.17: Sinusoid sign: M-mode examination of the visceral pleural surface shows a sinusoidal pattern (arrowheads) reflecting movement of the visceral pleural surface within the effusion

findings.[33,34] Remérand et al. described a multiplanar approach to measure PEV.[35] In their study, contiguous paravertebral intercostal spaces were scanned to detect the upper and the lower limits of the effusion. They showed good correlation of ultrasound PEV with either the volume of the drained pleural effusion or with CT based estimation of PEV.[35] The advantage of very accurate estimation of PEV remains to be established. In frontline critical care practice, it may suffice to identify the volume in qualitative terms, like small, moderate or large, to guide the intensivist in the management of the effusion.

Characterization of Pleural Fluid: Pleural fluid echogenicity, in combination with a patient's clinical history, gives important clues regarding its etiology. Transudates are generally anechoic. Exudative effusions have a variable amount of echogenicity. However, exudative effusions may occasionally be anechoic. Exudative effusions may demonstrate the plankton sign (see above) or swirling echoes and strands that give them a heterogeneously echogenic appearance. Highly cellular exudates like empyema or hemothorax can have a homogeneously echogenic appearance (Fig. 144.15B). Such richly cellular effusions can form a bilayer effect where the cellular components sediment in a dependent area within the effusion under gravitational effect (hematocrit sign, Fig. 144.15D). A complex parapneumonic effusion or empyema can be suspected by finding septations, loculations or stranding within the effusion (Figs 144.15A to C). Pleural ultrasonography is superior in identifying septations within pleural fluid compared to CT scan.[36]

Important Clinical Applications of Thoracic Ultrasonography

The knowledge of thoracic ultrasonography gives the intensivist the ability to immediately assess the critically ill patient at point of care. The clinician can immediately and repeatedly gather information or identify major problems more rapidly and accurately than can be obtained by the standard supine chest radiography. The reader is strongly encouraged to develop skill in thoracic ultrasonography and become proficient in its clinical application in the bedside management of their ICU patient.

Evaluation for Pneumothorax

Pneumothorax may occur in following procedures; may be an underlying cause for cardiopulmonary failure, and when it occurs in a patient on mechanical ventilatory support, it may be immediately life threatening due to tension physiology. Standard chest radiography is unreliable in diagnosing pneumothorax.[37,38-40] Thoracic ultrasonography is a reliable method to exclude pneumothorax with diagnostic performance that is comparable to the reference standard, CT scan[40,41] and superior to chest radiography. It may decrease the need for computed tomography.[42] The presence of sliding lung rules out pneumothorax at the site of examination with 100% negative predictive value.[43] The presence of lung pulse[14] or B lines rules out pneumothorax as the generation of these ultrasound signs depends on apposition of the two pleural surfaces.[10,16] In the supine position, free air in a pneumothorax space accumulates anteriorly (with the rare exception of loculated pneumothorax),[44] so, that rapid scanning at several points over the anterior lung zones rules out pneumothorax if lung sliding is present.

While the presence of lung sliding rules out pneumothorax in an absolute sense, its absence does not rule in pneumothorax. The absence of lung sliding or lung pulse is only suggestive of a pneumothorax. A pneumothorax interposes air between the visceral and parietal pleura so that lung sliding and lung pulse are lost. However, there are other causes of loss of lung sliding:

1. Pleural symphysis
2. Inadequate respirophasic expansion of lung: Dense consolidation, severe ARDS, advanced fibrosis, atelectasis from endobronchial occlusion, may all

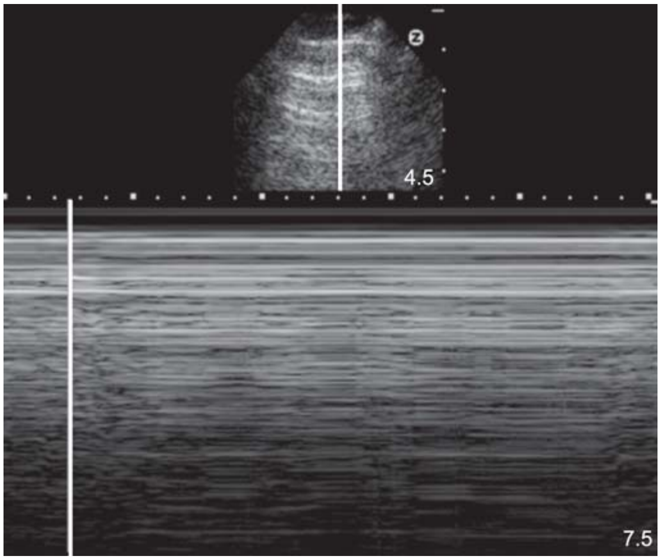

Fig. 144.18: M-mode examination of the lung in a case of pneumothorax. The absence of lung sliding is reflected by a straight pleural line (compare with image 144.11D to understand the difference). Also note the exclusive A-line pattern in the upper panel image

cause loss of lung sliding due to the fact that the underlying disease process restricts air entry during respiration. Lung pulse and B lines may still be present in these cases which is helpful. Apnea will result in loss of lung sliding although lung pulse continues until cardiac arrest supervenes.

When the intensivist checks for lung sliding immediately before central venous access or thoracentesis, the finding of loss of lung sliding immediately following the procedure is strong evidence of procedure related pneumothorax.[45,46] The absence of lung sliding can easily be documented on an M-mode examination of lung (Fig. 144.18).

While the absence of lung sliding can only suggest the presence of pneumothorax, thoracic ultrasonography may be used to diagnose pneumothorax if the intensivist can identify a “lung point”. In a pneumothorax space, the partially collapsed lung will still be apposed to the inside of the chest wall. If the ultrasound transducer is placed at the border of apposition, the partially collapsed lung will enter the scanning plane on an intermittent basis coincident with respiratory cycle. The operator will observe intermittent lung sliding or B lines, as the partially collapsed lung enters the scanning plane during the respiratory activity.[47] This sign is demonstrable at the border of the pneumothorax. The lung point can identify a small pneumothorax and can diagnose pneumothorax when a chest radiograph is nondiagnostic. The more lateral the lung point, the larger is the volume of the pneumothorax.[42] Lung point may be absent in a large pneumothorax with complete collapse of the lung. Identification of the lung point requires advanced scanning skills as it is a subtle finding, making it a specific, but not a sensitive finding.

A pneumothorax space is air filled and therefore has an exclusive A line pattern. The combination of absence of lung sliding with exclusive A line pattern has a high specificity for diagnosis of pneumothorax.[47,48]

Guidance for Thoracentesis

A major application of ultrasonography is for guidance of safe thoracentesis (see procedure section).

Clarification of Supine Chest Radiograph

Standard supine chest radiographs in the ICU are often difficult to interpret. The image is a two dimensional representation of a complex three-dimensional structure. Combined with the problems related to penetration and rotation artifacts, the resultant image gives a nonspecific summation radiodensity of the lung fields. Using ultrasonography, the examiner can rapidly and repeatedly develop a three-dimensional construct of the thoracic compartment that is superior to that derived from supine chest radiograph. By using an organized scan line protocol, thoracic ultrasonography can diagnose pneumothorax, normal aeration pattern, alveolar interstitial pattern, consolidation pattern and/or pleural effusion.

Ultrasound Assessment of Respiratory Decompensation

Acute respiratory failure is a common problem in the ICU. It may present in a patient who is breathing spontaneously or who is decompensating while already on mechanical ventilatory support. In either case, thoracic ultrasonography, when combined with basic Goal Directed Echocardiography (GDE) and lower extremity venous examination, helps the clinician to reach a diagnosis and decide upon an immediate management strategy. Lichtenstein et al. have demonstrated the excellent performance of thoracic ultrasonography for assessment of acute respiratory failure.[49] The authors proposed an algorithm for evaluation of patients with acute respiratory distress termed as “Bedside Lung Ultrasound in Emergency or the BLUE protocol”. Studying a cohort of 260 patients, thoracic ultrasound alone yielded correct diagnoses in 90.5% of cases. Integration of ultrasonography data with clinical assessment is likely to yield even better results.

Thoracic ultrasonography permits the intensivist to rapidly categorize the cause of acute respiratory failure. Pneumothorax, normal aeration pattern, alveolar-interstitial pattern, consolidation and/or pleural effusion are readily identified at the bedside of the decompensated patient. A very specific application of thoracic ultrasonography is in the management of the acutely dyspneic patient who may have respiratory failure due to cardiogenic pulmonary edema. Cardiogenic pulmonary edema results from elevation of hydrostatic pressure within the pulmonary capillary system due to elevation of left heart filling pressures. Lichtenstein et al. have demonstrated that presence of anterior A lines indicates that PAOP is ≤18 mm Hg and usually ≤13 mm Hg. Therefore, in an acutely dyspneic patient, presence of A lines, rules out cardiogenic pulmonary edema in an absolute sense. In an acutely dyspneic patient, anterior A line suggests airway disease, metabolic dysfunction, pulmonary embolism or neurological causes for the dyspnea. However, the presence of multiple anterior B lines is a nonspecific finding. Multiple anterior B lines may result from hydrostatic pulmonary edema, but may have many other potential causes.

Limitations of Thoracic Ultrasonography

Thoracic ultrasonography has some specific limitations:[11]

1. Obesity, edema, subcutaneous emphysema, chest wall dressings, wounds and body position all may prevent adequate image acquisition.
2. Some modern machines with extensive post acquisition image processing have near field clutter which degrades image quality.
3. Difficulty may arise in differentiating a complex pleural effusion from a consolidation. A hemothorax or empyema may be hyperechoic and lack dynamic findings. Air within a pleural effusion may further confuse the interpretation. With this complexity, chest CT may be required in this type of difficult cases. An air or fluid bronchogram supports a diagnosis of consolidation whereas a sinusoidal pattern on M-mode examination is typical of pleural effusion.[25]
4. Thoracic ultrasonography requires that the clinician is adequately trained in the field. For example, in identifying B lines, the examiner must have knowledge of their mimics: I and Z lines.[13] Sliding lung and lung point may be subtle findings.
5. Identification of a pleural effusion is straight forward if it is a large anechoic collection. On the other hand, an empyema or hemothorax may have dense homogenous echogenic pattern, similar to liver and spleen, without any visible septation. They may lack dynamic changes due to their density.
6. Application of lung ultrasonography results requires that the intensivist is able to integrate the findings into their overall analysis of pathophysiology and clinical circumstances.

CRITICAL CARE ECHOCARDIOGRAPHY

Introduction

Hemodynamic failure is a common feature of critical illness as is respiratory failure that derives from cardiac dysfunction. Echocardiographic assessment of hemodynamics is a key component of assessment and management of the critically ill patient. Mastery of Critical Care Echocardiography (CCE) is therefore an important component of Critical Care Ultrasonography (CCUS).

Basic CCE versus Advanced CCE

CCE may be divided into two levels of competence, basic and advanced. Basic CCE is a skill that can be acquired with a short period of training and should be considered as a standard part of competence in CCUS. Competence in advanced CCE requires a long period of training similar in scope to that required for cardiology echocardiographers. For the purpose of frontline critical care applications, we feel that most intensivists do not need advanced level competence in echocardiography. Most important clinical problems may be identified and managed by the intensivist with the basic level training.

Basic CCE uses rapid, real-time, visual two-dimensional assessment of cardiac structure and function with specific focused objectives.[50,51] It includes assessment of cardiac anatomy, global wall motion, biventricular function, gross valvular pathology, pericardium and IVC size (Table 144.3)[4]

Advanced CCE includes all elements of the basic examination with the comprehensive assessment of segmental wall function, valvular function and all elements of standard cardiology type Doppler examination (color and spectral). Advanced CCE also includes assessment of preload sensitivity and hemodynamic function, applications specific to critical care practice. Consensus competency guidelines for intensivists in advanced CCE has been published.[4]

Both basic and advanced CCE are performed within the context of the clinician being competent in the other aspects of CCUS. The value of the cardiac evaluation is amplified if the intensivist uses a whole body approach to CCUS.

TABLE 144.3: Competence in basic critical care echocardiography[4]

- Ability to recognize common echocardiographic patterns
- Ability to assess LV size and global systolic function
- Ability to recognize homogeneous and heterogeneous LV contraction pattern
- Ability to assess global RV size and contraction
- Assessment for pericardial fluid and diagnosis of tamponade
- IVC size and respiratory variation
- Basic color Doppler assessment for (severe) valvular regurgitation.

Equipment

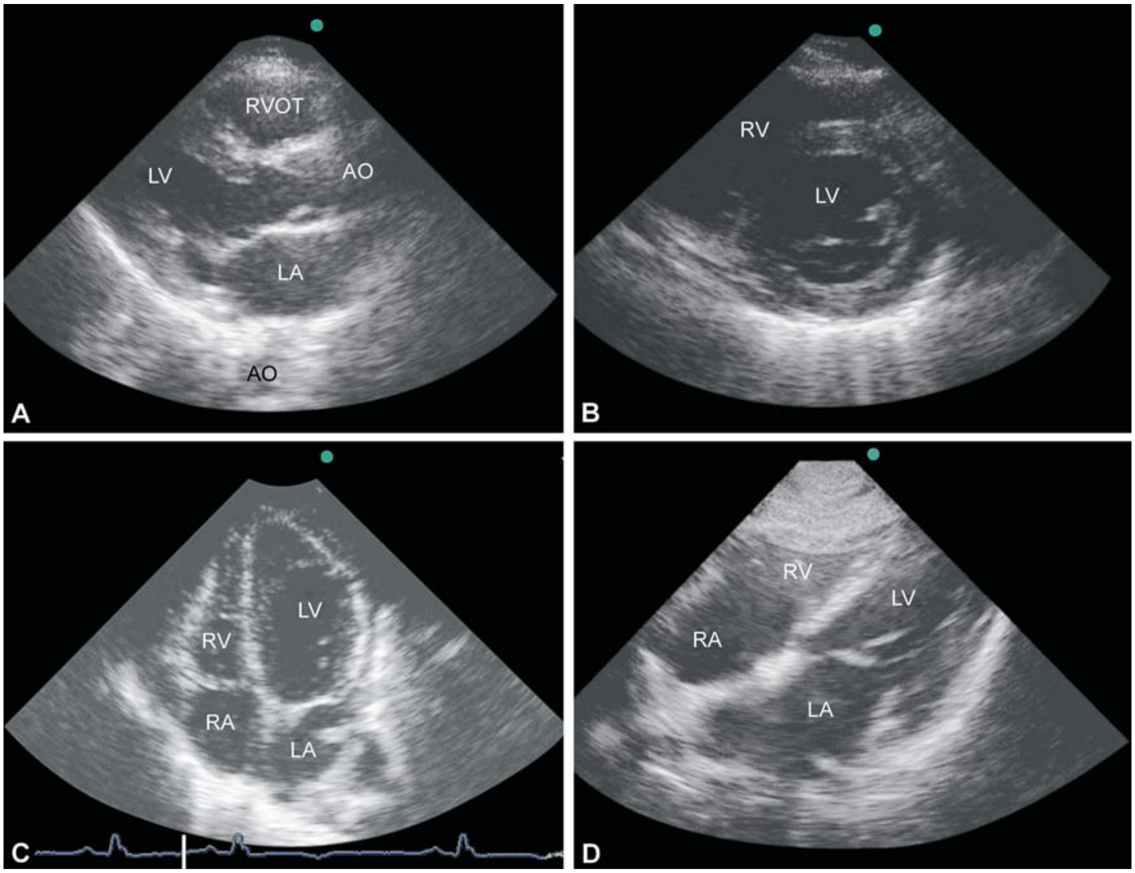
Both basic and advanced CCE require an ultrasonography machine capable of cardiac imaging, with a phased array transducer with the frequency range of 3.5–5.0 MHz. Phased array transducers used for cardiac ultrasonography have a small footprint, so, that they can scan between rib interspaces. Transducers used for cardiac ultrasonography are capable of performing other aspects of CCUS. Full Doppler capability is essential for performing advanced CCE. Basic CCE may be performed without Doppler capability.

Basic CCE

Image Acquisition

Basic CCE relies on five views that are used to answer limited number of clinical questions.

1. *Parasternal Longitudinal-axis View (PSL):* The transducer is placed in the left parasternal area, in the fourth intercostal space, with the index marker oriented towards the right shoulder. By gentle adjustment of probe angle and position, the examiner seeks a tomographic plane such that the image includes Right Ventricular Outflow Tract (RVOT), interventricular septum, left atrium, left ventricular outflow tract (LVOT), the Aortic Valve (AV) and the mitral valve (MV) (Fig. 144.19 A). An adequate PSL view bisects the aortic and mitral valves and includes the LV cavity in its longest axis. The PSL view allows



Figs 144.19A to D: Standard view in basic CCE. A. Parasternal long axis view; B. Parasternal short axis view; C. Apical four chamber view; D. Subcostal (four chamber) view

evaluation of Left Ventricular (LV) size and function, (RVOT), septal kinetics, valvular morphology and pericardial effusion

2. *Parasternal Short-Axis View (PSS):* Once an adequate PSL has been obtained, the transducer is rotated 90º clockwise without any angulation or tilting. This yields the PSS view. By gentle movement and angulation of the transducer, the examiner seeks to establish a cross sectional view of LV at the papillary muscle level, RV and interventricular septum (Fig. 144.19B). An adequate view positions the LV cavity at the center of the screen. The PSS view allows evaluation for pericardial effusion, global and segmental LV function and septal kinetics.
3. *Apical Four-Chamber View (A4C):* The transducer is placed at the LV apex with the index marker oriented towards left shoulder. By gentle movement and angulation of the transducer, the examiner seeks to establish a view from the apex of the RV, the LV, the Right Atrium (RA) and the left atrium (LA) that bisects the mitral orifice. In this view, both ventricles, both atria, interatrial and interventricular septa, the mitral valve and the Tricuspid Valve (TV) and pericardium can be visualized (Fig. 144.19C). The A4C view allows evaluation of RV/LV size and function, septal kinetics and pericardial effusion. This view has major utility in advanced CCE for Doppler based examination of mitral and tricuspid valves and segmental analysis. These are not within the scope of basic CCE.
4. *Subcostal View*: The transducer is placed below the xiphoid process with the index marker oriented towards the left flank. The transducer is held on its top surface in near horizontal position with the bottom surface contacting the patient. The subcostal view allows evaluation for RV/LV size and function, interatrial septal anatomy and function and pericardial effusion (Fig. 144.19D).
5. *Inferior Vena Cava (IVC) View:* The transducer is placed in the right paramedian subcostal position in order to scan the IVC in longitudinal axis. If air within the transverse colon blocks this view, the examiner may attempt a transcostal right paramedian longitudinal axis view or a right lower midaxillary longitudinal axis view. This view visualizes the IVC in longitudinal axis and is useful in assessing preload sensitivity.

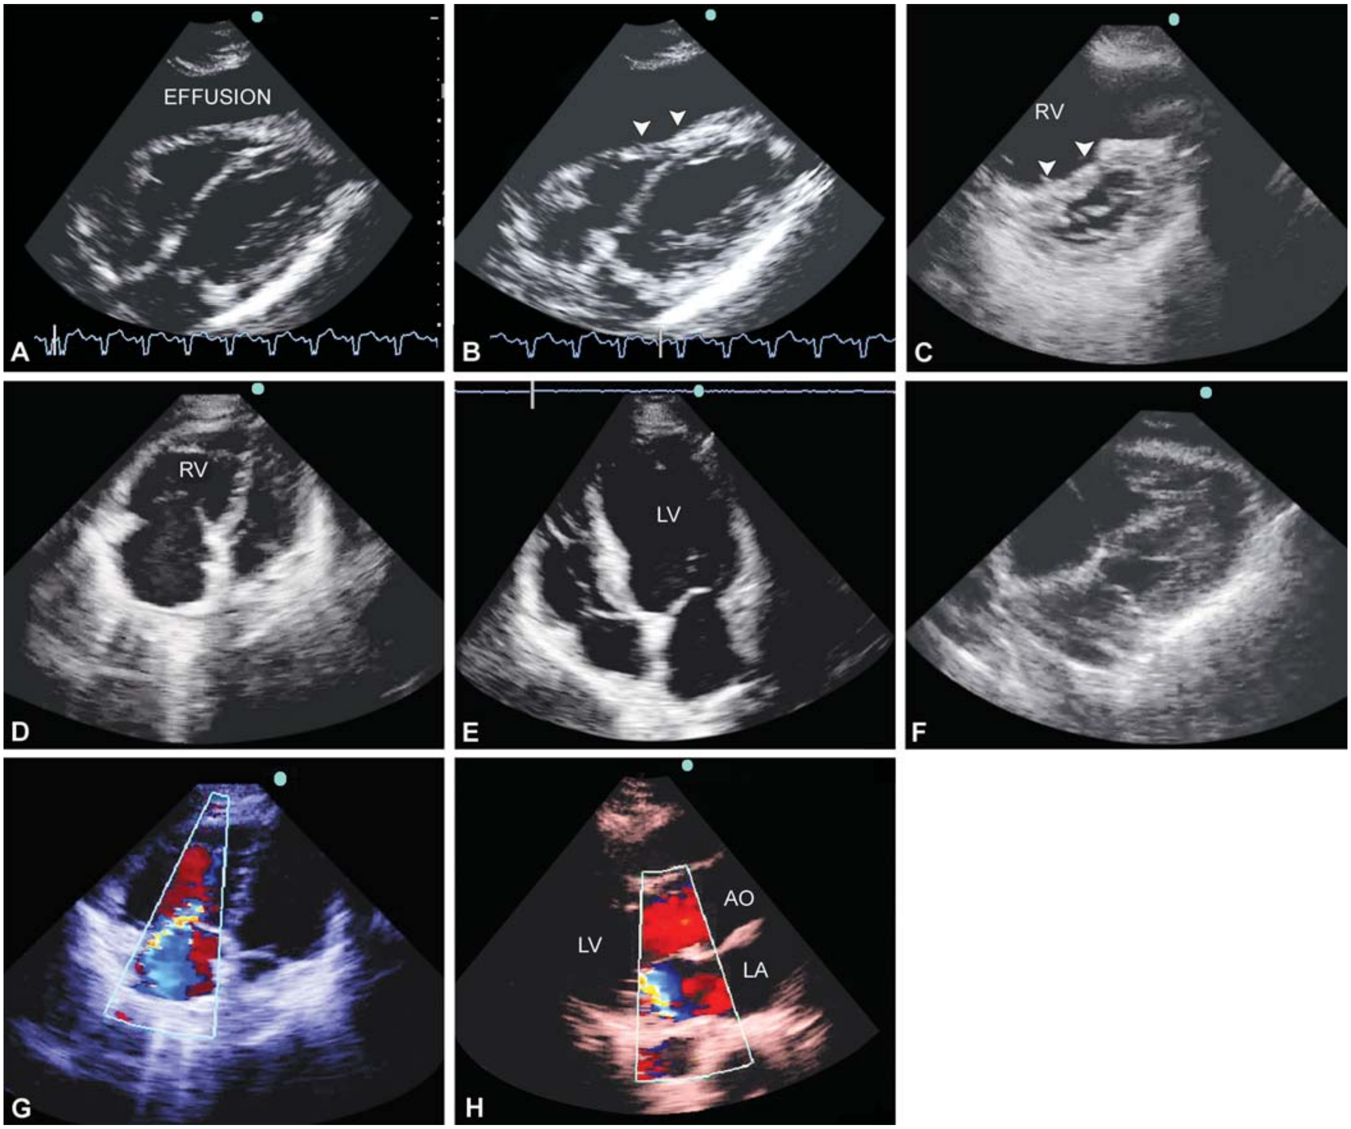
Competence in basic CCE may include qualitative assessment of valve function using color Doppler to assess for severe valvular regurgitation. Comprehensive assessment of valvular function is beyond the scope of basic CCE.

Challenges in image acquisition: Compared to other aspects of CCUS, image acquisition for CCE is more difficult. Ribs block transmission of ultrasound and so represent a barrier to easy examination. The air-filled lung blocks adequate examination and is often interposed between the transducer and the heart. Hyperinflation due to COPD or Positive End Expiratory Pressure (PEEP) may block all image acquisition from anterior chest and the examiner may have to rely on the subcostal image alone. In patients with obesity, heavy musculature, wounds or chest dressings, adequate examination may be blocked. Positioning the patient in lateral decubitus frequently improves image quality, but may be a major challenge in the ICU. Translational artifacts happen when the heart moves with respiratory movement. Patients who are dyspneic and who are on mechanical ventilation, have considerable movement of the heart during examination. The examiner may interpret changes as deriving from intrinsic cardiac contraction when they may represent movement of heart across tomographic planes related to respiratory translation. The position of the heart in the chest may result in suboptimal image acquisition. For instance, diaphragmatic elevation shifts the heart to a more vertically oriented position in the supine patient. Adequate PSL and PSS views are not possible in these circumstances.

In addition to the physical impediments, poor techniques may yield factitious information. For example, in an off-axis image of the LV in a PSL view, the small size of the LV cavity may cause the examiner to conclude that the patient has a hyperdynamic LV with endsystolic effacement suggesting severe hypovolemia. In the AP4, the size of the RV may appear to be very small if the transducer is rotated too far in the counterclockwise position.

Clinical Applications

Basic CCE is used for rapid assessment of cardiopulmonary failure. In approaching a patient in shock, the intensivist seeks to categorize the cause of the shock and to develop an initial management strategy. The frontline intensivist generally uses a simple differential diagnosis for the shock state; obstructive, cardiogenic, hypovolemic or distributive, with the understanding that these causes may frequently coexist. Basic CCE allows the intensivist to identify the primary cause of shock. The examination may be repeated in order to track the effect of the intervention. A few examples will highlight the use of basic CCE in assessment of shock. Obstructive shock may be caused by pericardial tamponade, or acute cor pulmonale due to massive



Figs 144.20A to H: Basic CCE in the differential diagnosis of shock. A. Large pericardial effusion; B. RV diastolic collapse in subcostal view (arrowheads). The ECG tracing and open position of the mitral valve show that the ventricles are in diastole; C. Large RV in parasternal short axis view. Note the leftward displacement of interventricular septum (arrowhead), giving the LV a 'D' shaped appearance and indicating RV pressure overload; D. Apical four chamber view showing RV dilatation. In this view, a normal RV is usually smaller than the LV; E. Large LV in a patient with poor LV function and hypotension; F. Small hypercontractile LV in a patient with hypovolemic shock. Note the complete effacement of LV cavity in systole; G. Color Doppler examination of tricuspid valve showing massive TR (A4C view); H. Color Doppler interrogation of mitral valve showing MR (PSL view).

pulmonary embolism (PE). In the former, the examiner identifies a pericardial effusion of consequential size (Fig. 144.20A). There may be accompanying signs of tamponade effect, like RV diastolic collapse or RA systolic collapse (Fig. 144.20B). In the right clinical context, the pericardial tamponade is identified and life saving pericariocentesis may proceed forthwith. In case of a patient with shock and a large hypocontractile RV (Figs 144.20C and D), massive PE is a major consideration. Lung ultrasonography with predominant A lines and presence of a DVT may confirm the diagnosis and lead to immediate intervention. Within the category of cardiogenic shock, severely impaired LV function will be identified (Fig. 144.20E). Occasionally, marked mechanical disruption of valve function and gross valvular regurgitation will be identified by the basic echocardiographer in a patient with cardiogenic shock (Figs 144.20G and H). Severe hypovolemic shock results in hyperdynamic LV with end systolic effacement of cavity

TABLE 144.4: Competence in basic CCE: Required cognitive skills in recognition of clinical syndromes

Severe hypovolemia
Small, hyperdynamic ventricles with end systolic cavity obliteration
Small (virtual) IVC, IVC with marked respiratory variation in caliber
LV pump failure
Global hypocontractility of LV suggests pump failure
Segmental hypocontractility suggests myocardial ischemia
LV cavity dilatation indicates chronic cardiac disease
RV failure
Acute cor pulmonale is manifested by RV dilatation and paradoxical septal motion
Isolated RV dilatation suggests RV infarct
Dilated, noncollapsible IVC is a corroborative finding
Cardiac Tamponade
Pericardial effusion (size inconsequential if tamponade is clinically suspected)
RA/RV diastolic collapse
Dilated, noncollapsible IVC supports the diagnosis
Acute massive left-sided valvular regurgitation
Normal LV cavity size (LV has no time to dilate)
Normal/hyperdynamic LV systolic function (LV volume overload)
Massive color Doppler regurgitant flow
Cardiac arrest: Clue to etiology (see text for details)
Tamponade
Acute cor pulmonale
Global LV systolic dysfunction
Heterogeneous contractility pattern

(Fig. 144.20F) and/or IVC that is very small in diameter (see below for detailed discussion of preload sensitivity). Distributive shock may present with relatively normal echocardiographic findings. It is obvious that echocardiographic findings must always be interpreted within the overall clinical situation. Chronic cardiac dysfunction may result in major abnormality on screening examination, but it may not be the primary cause of the shock state. Often, there may be more than one primary cause of hemodynamic failure. The integration of image acquisition, image interpretation and cognitive elements of CCUS are required for full application of echocardiographic findings at the bedside. An intensivist who becomes competent in basic CCE will be able to identify different clinical syndromes as listed in (Table 144.4).[4]

Advanced CCE

Advanced CCE allows for comprehensive assessment of cardiac structure and function. The intensivist with competence in advanced CCE has the same level of capability in image acquisition and interpretation as a cardiologist who is fully trained in echocardiography, with the exception of comprehensive assessment of prosthetic valve function, complex congenital heart disease, cardiac source of systemic embolism and stress echocardiography.[4] Beyond sophisticated image acquisition and interpretation skills, the practice of advanced CCE requires that the intensivist has a broad based knowledge of the pathophysiology of cardiopulmonary failure in order to integrate the findings into the care of the patient. The cognitive aspects of competence in advanced CCE and the key questions that can be addressed with advanced CCE have been defined in the ACCP-SRLF competence statement.[4]

Transesophageal echocardiography (TEE) may be an important component of competence in advanced CCE. In some countries, TEE is used on a routine basis by intensivists with both basic and advanced skill level. While this is a desirable practice pattern, we recognize that many ICUs do not have availability of TEE, particularly in North America. There are certain situations where TEE is superior to TTE. Patients with inadequate TTE image quality may require TEE for definitive evaluation of cardiac function. Obesity, edema, high PEEP levels and thoracic wounds or dressings may prohibit adequate TTE imaging. Especially problematic are patients who have thoracic trauma or are status post open heart surgery. Older studies report that TTE in the ICU leads to a successful examination in 50% of attempts[52,53] in comparison to TEE with success in 90% of attempts.[54] However, evolution of TTE technology in the form of high quality portable machines has greatly improved the yield of TTE in the critically ill patient. In our opinion, most patients in the medical ICU can be imaged adequately with TTE technique. The other indication of TEE is to examine cardiac structure and function that is not well imaged with TTE by virtue of its anatomic position. TEE is particularly suited for the detailed analysis of posterior cardiac structures such as the LA and the pulmonary veins with Doppler analysis. The superior vena cava is also better visualized with TEE.

Advanced CCE differs from basic CCE in that it focuses on quantitative analysis of cardiac function and structure whereas basic CCE gives the intensivist a qualitative assessment. Advanced CCE necessarily includes use of both color and spectral Doppler, whereas basic CCE does not. The use of Doppler requires that the intensivist has full knowledge of the physics of the technique as well as the limitations and pitfalls. Discussion of the physics, limitations and pitfalls of Doppler is beyond the scope of this discussion. Competence in advanced CCE requires many hundred hours of training and image interpretation under direct supervision of an experienced echocardiographer and supervisor.

Specific Components

Assessment of LV Structure and Function

a. *LV Volume:* End diastolic LV area may be measured in multiple axes and used for the identification of hypovolemia. The end diastolic area of the LV at papillary muscle level in the PSS view is a parameter that can be used to identify preload sensitivity (see below).[55] The measurement of LV end diastolic and end systolic areas may be used to measure stroke volume using Simpson's method.

b. *LV Contraction:* A global subjective assessment of LV function can be made and graded as hyperdynamic, normal, mildly reduced, moderately reduced or severely reduced. Visual estimate of Ejection Fraction (EF) may be made very accurately when compared to quantitative measurement of EF. Assessment of LV contractile function includes observation of LV segmental function based on a standard 17-segment model defined by the American Heart Association (AHA).[56] The visual analysis of segmental wall function is based on thickening of the wall segments and the endocardial excursion of the wall segment; excursion of >30% and wall thickening of >50% are considered normal.

c. M-mode analysis of cardiac function is a part of advanced CCE. It is useful for detailed analysis of high frequency cardiac functions such as valve fluttering, premature coaptation of valve leaflets, systolic anterior motion of mitral valve, mitral valve prolapse, septal kinetics and pulmonary valve function. The utility of M-mode examination of ventricular function has major limitations in the assessment of fractional shortening and EF related to the complex three dimensional structure of the heart and the possibility of asymmetric segmental wall function.

d. Stroke volume (SV) may be measured both with TTE and TEE. Typically, it is measured in the LVOT but may be measured at other valve orifices, if the examiner seeks to measure quantitative valve regurgitation/stenosis or for shunt physiology. Once SV is measured, cardiac output is known and multiple hemodynamic indices can be derived using standard formula such as systemic vascular resistance, pulmonary vascular resistance and indices of ventricular work.

   The SV is ascertained by measuring the LVOT diameter from PSL view (Fig. 144.21A). The diameter is used to calculate the area of LVOT. From A4P view, the transducer is angled anteriorly to obtain an apical five chamber view that includes the LVOT (Fig. 144.21B). A pulsed wave Doppler interrogation box is placed in the LVOT and the resultant velocity envelope is integrated to yield the Velocity Time Integral (VTI). SV is calculated as follows (Figs 144.21C and D):

   SV (ml) = LVOT area (cm^2) x VTI area (cm)
   LVOT cross-sectional area=LVOT radius)^2 x 3.14
   (LVOT is assumed as a circle, the area therefore being represented by the formula πr^2)

e. Other measures of LV systolic function may be derived from Doppler assessment. In presence of mitral regurgitation (MR), continuous wave Doppler examination of the MR jet permits calculation of the rate of pressure increase (dP/dt) within the LV during isovolumetric contraction. This dP/dt is sensitive to changes in contractility and is independent of preload or afterload.[57] Systolic mitral annular descent measured by tissue Doppler gives an estimate of global LV function.[58]

f. Assessment of LV diastolic function is based on Doppler assessment of transmitral filling, pulmonary venous flow pattern and lateral mitral annular velocity. These values may be used for quantitative assessment of PAOP. Use of TEE is particularly suited for detailed analysis of pulmonary vein inflow, the results of which may be used to estimate PAOP.

Assessment of RV Structure and Function

RV diastolic overload is manifested as RV dilatation. It can impair LV diastolic function, can contribute to hemodynamic failure, and has implications when assessing a patient for fluid therapy. A visual comparison of LV and RV size and RV cavity shape gives qualitative information about RV diastolic overload. A normal RV is smaller than the LV and crescentric in shape from PSS view (Fig. 144.20B). Both ventricular areas can be measured at end diastole from an A4C view. Other authors have used the subcostal view.[59] The normal RVEDA:LVEDA ratio is between 0.36 and 0.6 (0.48±0.12).[60] Moderate dilatation is defined as ratio 0.7–0.9 and severe dilatation as ratio >1. Some authors have shown that visual analysis of RV dilatation by a trained echocardiographer correlates well

with quantitative measurement.[61] RV diastolic dysfunction results in a characteristic septal dyskinesia pattern measured with M-mode and that is identified as septal paradox by 2D echocardiography.

Assessment of RV systolic function is based on a qualitative visual analysis of RV free wall and interventricular septum contraction. The contractile function can be graded as normal, mild, moderate or severely reduced. In a patient with abnormal RV systolic function, evidence of RV systolic overload may be present. Septal dyskinesia is the hallmark of RV systolic overload. Septal dyskinesia results when an increase in RV afterload leads to a prolongation in RV contraction beyond the end of LV ejection. This leads to a transient increase in RV pressure over LV pressure when RV is still contracting though LV has started to relax. This leads to a posterior movement of the interventricular septum.[62] This paradoxical septal motion can be observed visually and can be more precisely recorded by M-mode at mid-ventricular level from a PSL view. Septal dyskinesia can also be diagnosed by measuring systolic Eccentricity Index (EI). From a PSS view of the LV at papillary muscle level, measurements are taken at end-systole. D1 is measured as a diameter that bisects the papillary muscles and D2 as an orthogonal diameter to D1. D2/D1 is taken as the EI. A normal systolic EI is 1; EI > 1 indicates septal dyskinesia.[63]

RV free wall thickness is assessed at end diastole on the subcostal view. The normal thickness is 3.3 ± 0.6 mm. In presence of features of RV systolic overload, significant thickening of RV free wall helps to differentiate between acute and subacute/chronic cor pulmonale.

Assessment of Valve Function

Advanced CCE permits comprehensive assessment of valve function. This may be an important component of assessment of a patient with cardiopulmonary failure. In the ICU, major valve failure may be the cause of the problem. Alternatively, presence of significant valve dysfunction may contribute to compromise of hemodynamics in the patient who has another life-threatening disorder. The comprehensive assessment of valvular function requires competence in detailed 2D assessment of the anatomy of the valve apparatus. This includes identification of valve vegetations and their mimics, as well as subtle findings as such as valve thickening and disruption of paravalvular structures. Complete evaluation of prosthetic valve anatomy and function requires a highly competent echocardiographer who has specific training in the subject. The intensivist with competence in advanced CCE may provide screening service but may wish to call for consultation in this situation. Generally speaking TEE is required for full evaluation of prosthetic valve function.

The evaluation of valve function starts with 2D assessment and color Doppler analysis. If significant valvular dysfunction is suspected, spectral Doppler analysis allows for quantification of both stenotic and regurtitation dysfunction. Color Doppler is frequently used in a qualitative fashion to grade the degree of valve regurgitation. Methods of quantitative assessment include use of continuity method, the proximal isovelocity surface area method and/or measurement of vena contracta. Identification of significant stenosis or regurgitation includes determination of the possible etiology such as endocarditis, rheumatic heart disease, subvalvular stenosis, congenital lesion, chordae/papillary muscle dysfunction, etc.

Examination of Cardiac Pressures

Advanced CCE has in common with standard cardiology echo the measurement of a wide variety of cardiac pressures. Using spectral Doppler, the intensivist can accurately measure such pressures as pulmonary artery systolic pressure, pulmonary artery diastolic pressure, left atrial pressure, left ventricular end diastolic pressure, etc. Generally, measurement of cardiac pressures with Doppler requires that there will be some degree of valvular regurgitation or stenosis.

Examination of Pericardial Space

The identification of pericardial effusion and qualitative identification of RV and/or RA compression is part of the skill set for basic CCE. Advanced CCE allows the intensivist to examine other features to identify more precisely findings that favor the presence of cardiac tamponade physiology. The use of M-mode permits accurate timing of wall movement of the RV and RA free wall in the PSS, subcostal, A4C views. Tamponade physiology is suggested by diastolic collapse of the RV free wall and/or systolic collapse of RA free wall. Tamponade physiology causes increased variation in MV and TV inflow velocities during respiratory cycling. Neither chamber compression nor variation of diastolic inflow is highly specific or sensitive for presence of tamponade and multiple confounders may be present in any given patient. The diagnosis of cardiac tamponade cannot be made by echo alone but rather is based on the clinical context.

Clinical Applications

It is beyond the scope of this discussion to review all aspects of advanced CCE that are relevant to critical care practice. What follows is a review of two important components of advanced CCE that are of particular interest to the intensivist but are not often included in the cardiologist performed echocardiography: identification of preload sensitivity and measurement of stroke volume and its derived indices.

When managing a patient with shock, a key question is whether an infusion of volume will result in improved Cardiac Output (CO)/Stroke Volume (SV); in other words, whether the patient is volume responsive (preload sensitive) or not. This is a key question for the clinician, as volume resuscitation may be of great benefit to a patient in shock but dangerous if given in the wrong circumstance. For example, a patient with acute cor pulmonale and massively dilated RV who is in shock should not receive volume resuscitation as further RV dilatation will restrict LV filling and result in worsening hemodynamic function. Inappropriate volume resuscitation has been associated with poor outcome.[64] There are several approaches to identifying whether the patient in shock is volume responsive. From a physiological point of view, the clinician seeks to determine whether the ventricles are on the steep portion of the Frank-Starling curve (where there will be SV augmentation with volume resuscitation) or whether they are on the flat portion (where volume infusion will not increase SV). In some clinical situations, the need for volume is clear from the history (e.g. history of blood loss, vomiting, diarrhea, etc.) and physical examination (e.g. poor skin turgor); in such cases, volume replacement is clearly warranted and can be undertaken without any further study.

A traditional approach to identify volume responsiveness is the static measurement of pressures. Both CVP and PAOP are now known to be poor predictors of volume responsiveness with the exception of the occasional patient who has very low cardiac filling pressures.[65,66] The end diastolic LV diameter and area are criteria that can be used for identification of volume responsiveness; an end-diastolic LV diameter of <25 mm and LV end diastolic area of <55 cm^2 are criteria used for diagnosis of hypovolemia.[55] End-systolic cavity obliteration is also a sensitive sign of hypovolemia and low preload.[67]

Advanced CCE permits the intensivist to make a variety of dynamic measurements that predict volume responsive shock with a high level of accuracy. Dynamic parameters to identify preload sensitivity are based on the premise that a change in preload will change the SV (or its surrogate CO) if the patient in situated on the ascending portion of the Frank-Starling curve. Based upon these parameters, the clinician may identify a patient as being preload sensitive before administering volume resuscitation. This avoids unnecessary and potentially harmful volume infusion.

Michard et al. showed that significant variations in pulse pressure in patients on mechanical ventilatory support identify preload responsiveness.[68] The patients had to be passive on mechanical ventilatory support and in sinus rhythm. An arterial PP variation between inhalation and exhalation of more than 12% is strongly predictive of preload sensitivity and far superior to common static pressure measurements. Pulse pressure in this situation is directly proportional to SV, so, that the observation of significant pulse pressure variation actually represents a significant variation of SV. Using this information, the advanced echocardiographer may examine directly the variation of SV in reference to cyclical variation of intrathoracic pressure in a patient on mechanical ventilation provided the patient is passive and in regular cardiac rhythm. The ventilator, by increasing intrathoracic pressure during inspiration, alters the preload of ventricles. Elevation of intrathoracic pressure during inspiration has the effect of reducing preload of the RV and augmenting the preload of the LV; during exhalation the effect is reversed. Therefore during mechanical ventilation, if SV that is measured by real time echo varies to a significant extent, there is a high probability that the patient will have augmentation of SV following volume infusion. If there is a lack of change in SV, the patient will not have augmentation of SV following volume infusion and therefore should not receive it.

As a surrogate of SV, Feissel et al. has used the VTI or flow velocity measured in the descending aorta.[69] This technique requires a transesophageal Doppler transducer and is less practical than measuring SV directly at LVOT by TTE. A variation of greater than 12% in SV, VTI or the flow velocity in this position indicates that the patient in shock will have improvement in SV and therefore CO following volume resuscitation.

The method of measuring SV variation with respiration has been shown to be useful only in patients who are passive on ventilatory support in normal rhythm and therefore has limited application. An alternative technique, which has been shown to be effective in spontaneously breathing patients, uses passive leg raising (PLR). Raising both legs in the supine patient to 45° results in rapid augmentation of venous return to the heart. With this simple maneuver, about 300 ml blood is delivered to the intrathoracic compartment constituting a major volume challenge which is completely reversible when legs are lowered. In performing the PLR maneuver, the intensivist measures the LVOT VTI, before and one minute after the maneuver. A PLR-induced increase in SV of >12% has been shown to be predictive of central hypovolemia; the same also predicted an increase in stroke volume of >15% in response to volume expansion.[70,71]

Measurement of SV variation during ventilator cycling or with PLR requires advanced CCE skills. It may be limited by poor image quality and takes time. These limitations have encouraged investigators to look for a simpler noninvasive surrogate of aortic VTI and LV SV volume. Brachial artery peak velocity ($Vpeak_{brach}$) is one such parameter that can be measured using Doppler. Monge Garcia et al. have studied respiratory variation of brachial artery peak velocity ($\Delta Vpeak_{brach}$) to predict fluid responsiveness in mechanically ventilated patients.[72] A $\Delta Vpeak_{brach}$ value >10% predicted fluid responsiveness, defined as ≥15% increase in SV index, after volume expansion with a sensitivity of 74% and a specificity of 95% (Fig. 144.22). Préau et al. has shown that PLR combined with measurement of change in femoral artery flow velocity is useful in identifying

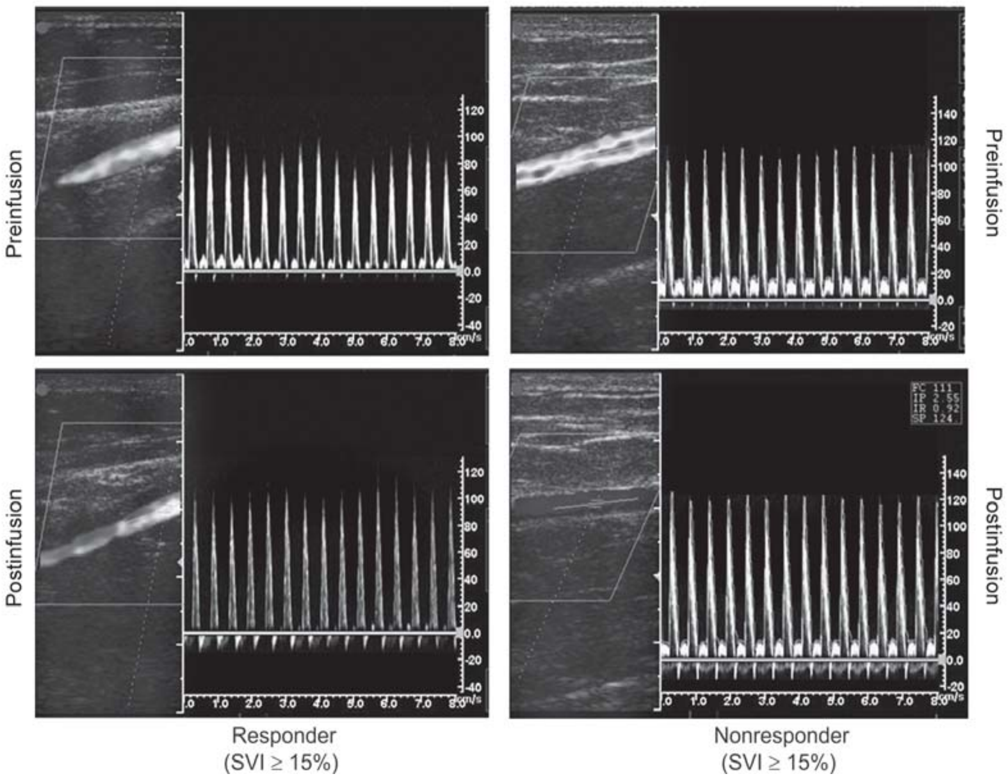

Fig. 144.22: Illustrative example of Doppler evaluation of brachial artery peak velocity variation in a responder patient and nonresponder patient. In the responder patient (left), volume expansion (VE) induced a decrease of brachial artery peak velocity variation ($\Delta Vpeak_{brach}$) by 15% (from 23% at baseline to 8% after VE). Response to volume challenge was evident in 27% increase in stroke volume index in this patient (not shown in the figure). In the nonresponder patient (right), volume expansion did not induce any significant change in $\Delta Vpeak_{brach}$ (from 9% to 9% after VE). Stroke volume index increased only 8% after VE in this patient (*Source*: Reproduced from Monge Garcia MI, Gil Cano A, Diaz Monrove JC. Brachial artery peak velocity variation to predict fluid responsiveness in mechanically ventilated patients. Crit Care. 2009; 13:R142. Original publisher BioMed Central Ltd. Image reproduced within the scope of open access policy of BioMed Central)

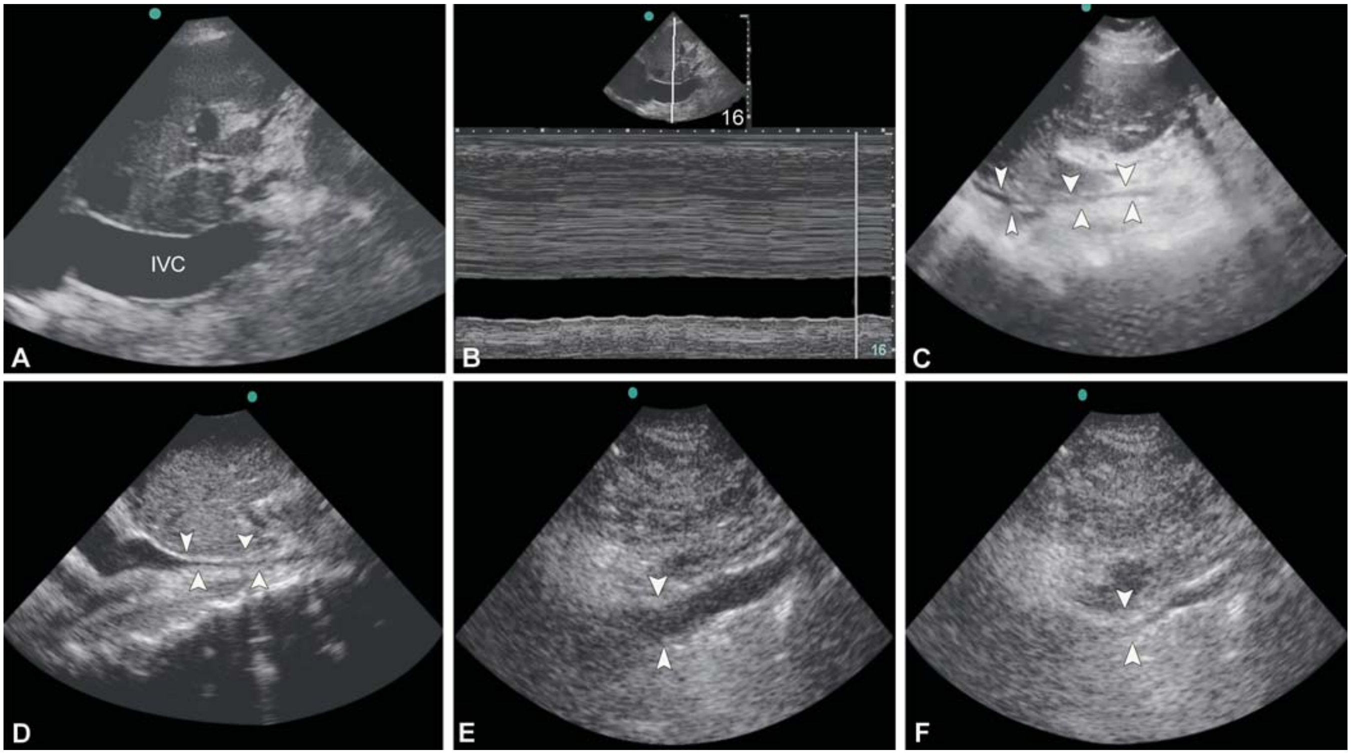
preload sensitivity in spontaneously breathing patients.[73] Conceptually, variation in brachial artery or femoral artery flow is similar to measurement of pulse pressure variation with an arterial catheter and has the major advantage that it can be performed easily by clinicians with minimal training in ultrasonography.[74]

Lung ultrasonography has a role in guiding volume resuscitation in critically ill patients with shock. If such a patient has A line predominance in anterior lung zone, Lichtenstein et al. have demonstrated that PAOP is ≤18 mm Hg and in high proportion of cases ≤13 mm Hg.[21] The presence of A line predominance does not indicate the need of volume resuscitation, but indicates that volume resuscitation can be given to the patient without concern that it will cause elevation of left sided filling pressures.

Assessment of IVC size and its variation with respiration have been used to predict fluid responsiveness (Figs 144.23A to F). The exact location used for measurement of IVC diameter varies in different reports.[75,76-78,79-82] IVC diameter can be measured 2–3 cm from the right atrium in a longitudinal view. For accurate measurements, an M-mode tracing, perpendicular to the IVC is used (Fig. 144.23B). An IVC diameter of <10 mm may predict a positive response to fluid infusion.[81] Cut-off values for the difference in IVC diameter between inspiration and expiration of 12% (using max-min/mean) and 18% (using max-min/min) for IVC have been reported to accurately separate responders from nonresponders.[78,81] The above measures have been validated only in patients who are passive on mechanical ventilation, in regular rhythm and who have normal RV function.

Variation of superior vena cava size coincident with ventilator cycling may also be used to predict preload sensitivity.[83] This requires use of TEE.



Figs 144.23A to F: IVC diameter and its variation help to predict fluid responsiveness. A. Large dilated IVC; B. M-mode examination of the IVC shows little respiratory variation of diameter; C and D. Very small or 'virtual' IVC (arrowheads) in a volume depleted patient; E and F: Significant respiratory variation of IVC diameter during mechanical ventilation in a volume depleted patient. E shows IVC diameter in inspiration and F shows IVC diameter in expiration

ABDOMINAL ULTRASOUND: SCOPE IN ICU

Abdominal ultrasonography has important, but limited applications in the ICU. It is neither necessary nor realistic for the intensivist to become fully trained in all aspects of abdominal ultrasonography. Abdominal ultrasonography is used to answer important specific questions; so, the modality is best deployed as a screening tool. As the intensivist uses ultrasonography for screening purposes, they must understand when to refer the patient for more complete study by a fully trained ultrasonographer. Abdominal ultrasonography has specific technical limitations and abdominal CT may be required for definitive imaging. However, abdominal CT requires transport of the unstable patient, has considerable radiation dose, and cannot be preformed repeatedly. Ultrasonography is performed quickly at the bedside and answers certain clinical questions with a high level of accuracy. Schachrer et al. reported the experience of 400 ultrasonography examinations in the ICU.[84] New pathological findings were detected in one third of cases with confirmation of known pathology in another third. In 80% of cases, no other imaging test had to be performed. We will review the aspects of abdominal ultrasonography that are relevant to the intensivist.

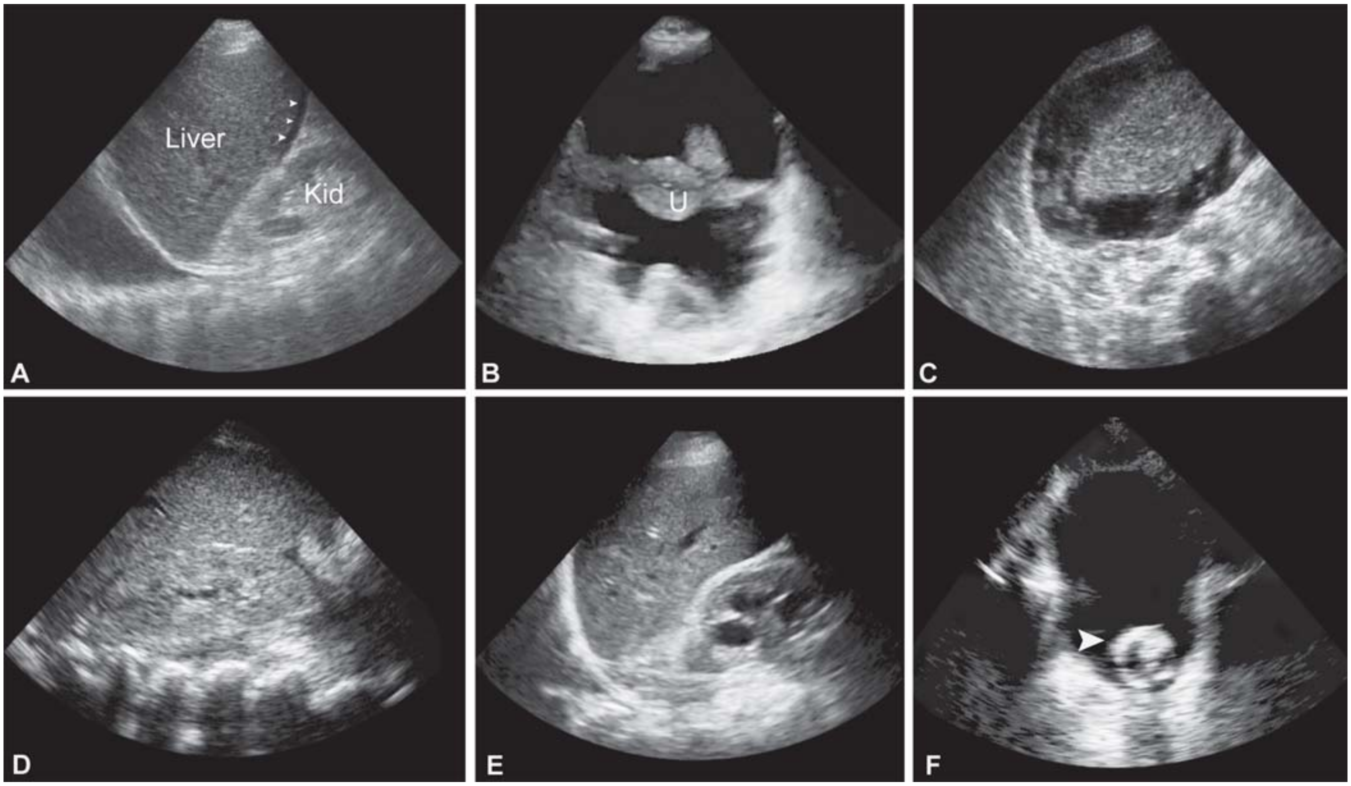
Equipment

Modern portable machines have full capability for abdominal ultrasonography. Doppler is not required for applications typical to the ICU. A curved array transducer that is specifically designed for abdominal ultrasonography is desirable, but adds significant cost to the purchase price of the ICU machine. A phased array cardiac transducer provides acceptable image quality while reducing acquisition cost.

Clinical Applications

Identification of Intraabdominal Fluid (Ascites)

A focused abdominal ultrasound examination performed by nonradiologists originated from the concept of Focused Assessment with Sonography for Trauma (FAST).[85,86] The FAST is a limited abdominal examination performed by emergency department physicians or trauma surgeons specifically to determine whether the



Figs 144.24A to F: Common applications of abdominal ultrasound in critical care unit. A. Minimal ascites in the hepatorenal recess (arrowheads). In a patient with blunt abdominal trauma, such findings are highly significant; B. Pelvic scan showing large amount of anechoic ascites (uterus is indicated by U); C. Complex ascites. Echogenic ascitic fluid may indicate exudative and often infected ascitic fluid; D. Small kidney with loss of corticomedullary differentiation in a patient with chronic renal failure; E. Hydronephrosis of right kidney; F. Distended urinary bladder in a patient with blocked Foley's catheter. The balloon of the catheter can be seen inside the distended bladder (arrowhead)

patient has intra-abdominal fluid collection. Ultrasonography can detect as little as 100 cc of free fluid in the peritoneal cavity.[87] The FAST protocol was developed to detect blood in patients with blunt abdominal trauma. It consists of three abdominal views; examination of the hepatorenal recess, the splenorenal recess and the rectovesical/rectovaginal region. A variation of the FAST examination includes a subxiphoid window for pericardial fluid and examination of the aorta. The FAST examination has reduced the need of diagnostic peritoneal lavage in trauma patients.[88]

The FAST exam has utility in the ICU, as the presence of ascites has implications for diagnosis and management. Identification of ascites requires the operator to perform the standard components of FAST exam. In addition, the intensivist should examine the paracolic gutter and subphrenic regions for a more comprehensive evaluation (Figs 144.24A and B). Ascites is hypoechoic, subtended by typical anatomic boundaries (intra-abdominal organs) and has typical dynamic findings. Unlike pleural fluid, it undergoes shape change with force application by the transducer on the abdominal wall. Mimickers of ascites include fluid-filled intestine, distended bladder and distended gall bladder. Anechoic ascites (Fig. 144.24B) is generally transudative while exudative ascites is often hyperechoic. Ultrasound cannot differentiate between fresh blood and ascitic fluid as both are usually anechoic. The presence of fluid with echogenicity or internal loculations/septations usually indicates an exudate and suggests need for further investigation (Fig. 144.24C). Identification of ascites is an important ultrasound finding in itself but always has to be interpreted within the clinical context. A patient with cirrhosis and a large amount of anechoic fluid may not require further diagnostic evaluation. Intra-abdominal fluid with increased echogenicity and loculations, combined with signs of sepsis or findings of acute abdominal presentation, suggests peritonitis with hollow viscous perforation or a neglected hemoperitoneum. The identification of ascites mandates a decision whether to perform paracentesis as part of a diagnostic or therapeutic response.

Evaluation of Kidneys: Both the kidneys can be readily imaged at the bedside in the ICU. The optimal position for kidney imaging is with the patient in lateral decubitus position. This is usually not feasible in the critically ill patient because of hemodynamic and respiratory instability. Given this limitation, the left kidney may be difficult to image in the supine position. The operator may need to hold the transducer placed close to posterior axillary line. The examination starts with the longitudinal axis view of the kidneys followed by transverse axis imaging. A single tomographic plane is not sufficient and the intensivist should scan through the organs in multiple tomographic planes in order to develop a three dimensional construct of the kidneys. The longitudinal length, parenchymal thickness, parenchymal echogenicity and corticomedullary differentiation are determined. Normal longitudinal length is 9–12 cm; normal cortical thickness is between 1.5–1.8 cm. Normal renal cortex is hypoechoic or isoechoic compared to the liver or spleen. A visible distinction between the cortex and the medulla is normal. Renal parenchyma surrounds the renal sinus which contains the pelvis, the calyces and major branches of renal vasculature. It appears hyperechoic because of the presence of fatty tissue.

Ultrasonography is the preferred imaging modality for patients with acute renal failure in the ICU. A primary objective of the examination is to rule out obstructive uropathy as the cause of renal failure. A dilated pelvicalyceal system indicates obstructive uropathy and can be diagnosed with high level of sensitivity (Fig. 144.24E). The severity of the obstruction may be classified and its chronicity can be estimated by the morphologic characteristics of the dilatation. Stones within the collecting system may be observed with accompanying acoustic shadow artifact. There may be pitfalls in the examination for hydronephrosis. A patient with significant coexistent intrinsic renal parenchymal disease, who also has a urinary obstruction, may not develop hydronephosis due to lack of urine production. Rarely, infiltrative diseases of the kidney may restrict pelvicalyceal dilatation in the obstructed kidney. Acute obstruction will not result in discernible hydronephrosis immediately and the finding may be delayed for many hours.

Acute kidney injury with renal failure results in normal or enlarged kidney size. Chronic renal disease causes increased cortical echogenicity and reduction in cortical thickness (Fig. 144.24 D).

A problem facing intensivists in performing renal ultrasonography is the discovery of an abnormality that is beyond their level of competence. Renal cysts, both simple and complicated, unusual variants of normal anatomy or malignancy, may present as ambiguous findings on ultrasound examination when the intensivists' primary concern is to rule out obstruction. In this case, the screening ultrasonographer has an obligation to call for a definitive examination by a fully trained ultrasonographer or by other diagnostic modalities like CT scan.

Evaluation of the Urinary Bladder

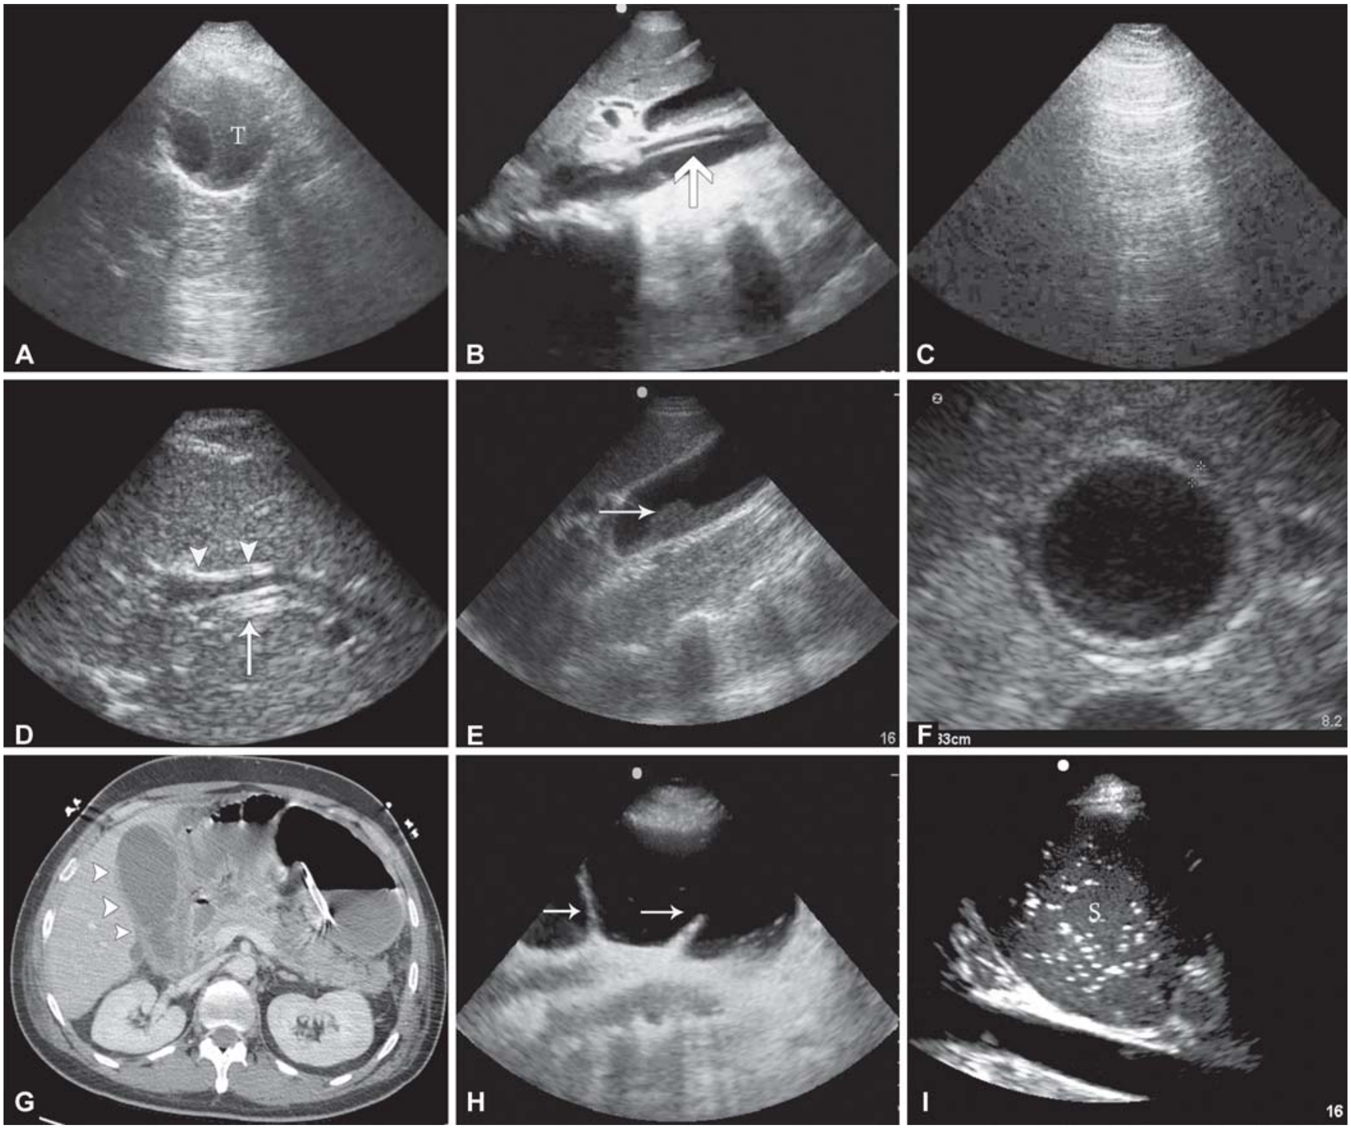
The urinary bladder is readily imaged using a transverse and longitudinal axis approach at the suprapubic area. The distended bladder appears as a large anechoic space in the appropriate anatomic location (Fig. 144.24 F). A primary indication for bladder ultrasonography is in the evaluation of anuria. This often results from blockage or misplacement of a urinary catheter. In the case of a blocked urinary catheter, the fluid filled catheter balloon is readily visualized in the distended bladder (Fig. 144.24F). Flushing or manipulating the catheter will result in renewed urine flow in these cases. The examination of the urinary bladder should always be performed in conjunction with the kidneys. In imaging the urinary bladder, the intensivist must be prepared for the possibility of ambiguous ultrasonography findings, such as bladder tumor. Just as is the case with the kidneys, this requires definitive imaging by a fully trained ultrasonographer.

Evaluation of Abdominal Aorta

The Abdominal aorta may be imaged in both longitudinal and transverse axis in order to determine whether an aortic aneurysm or other major pathology exists (Figs 144.25A and B). An enlarged aorta (>3 cm, measured from outside wall to outside wall) with luminal thrombus and irregularity suggests an aortic aneurysm.

Evaluation for Pneumoperitoneum

Ultrasonography has been described as a more sensitive modality than plain radiography for the diagnosis of pneumoperitoneum with a high sensitivity, specificity and positive predictive value.[89,90] To detect pneumoperitoneum, the epigastric area and right upper quadrant are scanned in the supine patient. Sonographically, air will appear as echogenic areas with posterior reverberation artifacts.[91,92] Pneumoperitoneum also causes enhancement of the peritoneal stripe.[93] Presence of air bubbles within ascitic fluid will also point to a diagnosis of pneumoperitoneum.[92] A lack of peritoneal



Figs 144.25A to I: Other applications of abdominal ultrasound. A. Abdominal aortic aneurysm with partial thrombosis of the lumen (T); B. Aortic dissection, the intimal flap can be seen in this longitudinal view of the aorta (arrow); C. A case of pneumoperitoneum. Note that no abdominal organ could be visualized in this upper abdominal scan. Exclusive air pattern, as seen in this photo, can raise the suspicion of pneumoperitoneum in the right clinical scenario; D. Dilated intrahepatic biliary duct in a case of obstructive jaundice (arrowheads). Note that the accompanying normal looking portal vein branch (arrow); E. Gallbladder sludge (arrow); F. Dilated gallbladder with thickened wall in a case of acalculous cholecystitis; G. Abdominal CT scan of the patient in F shows large dilated gallbladder (arrowheads); H. Dilated loop of colon. Note the colonic haustra (arrow); I. Dilated fluid filled stomach seen in a preintubation scan (S).

sliding also indicates the possibility of pneumoperitoneum. Massive pneumoperitoneum may make it impossible to visualize any abdominal organ, indirectly suggesting the diagnosis (Fig. 144.25C).

Evaluation of Other Abdominal Organ Systems

Ultrasonography may be used to assess all organ systems within the abdomen. However, the intensivist needs to be aware that developing comprehensive skill in all aspects of abdominal ultrasonography requires dedicated and time consuming training. The authors suggest that this is not necessary for routine critical care function. The intensivists may appropriately limit abdominal ultrasonography to a specific targeted screening approach.

The liver is imaged in longitudinal and transverse planes. If sepsis is suspected, assessment of liver can give valuable clues like presence of single or multiple hypoechoic lesions may be indicative of abscesses. For suspected biliary disease, ultrasonography is the initial investigation of choice. Intrahepatic biliary ductal dilatation is the hallmark of obstructive biliary pathology (Fig. 144.25 D). In patients with jaundice, abnormal liver function tests, sepsis of unknown etiology or new fever, biliary ductal dilatation assumes importance. The gallbladder should be imaged in multiple tomographic planes to look for stone and biliary sludge (Fig. 144.25E). Features of acute cholecystitis include gallbladder wall thickening, pericholecystic fluid and sonographic elicitation of Murphy's sign. In the absence of stone, the above signs along with an enlarged gallbladder indicate a possible diagnosis of acalculous cholecystitis[94] (Fig. 144.25F and G). Evidence of gallbladder stone, sludge and biliary obstruction has important implications in a patient admitted with pancreatitis.

Ultrasonography is useful for evaluation of the gastrointestinal tract; for example, typical finding of enteritis include thickened bowel wall (>4 mm) and echoic bowel content. Toxic megacolon may be identified by imaging fluid filled ascending colon greater than 10 cm in diameter (Fig. 144.25 H). The presence of bowel peristalsis by ultrasonography rules out ischemic bowel or peritonitis with a high level of certainty.

The pancreas is frequently difficult to image with ultrasonography in the poorly prepared critically ill patient. Identification of retroperitoneal pathology, such as retroperitoneal LN or hematoma, is also challenging to anyone other than a fully trained ultrasonographer. The spleen may be readily imaged for such abnormalities as abscess but much splenic pathology is not readily visible to a screening ultrasonographer, e.g. splenic hematoma may be isoechoic to adjacent normal splenic parenchyma.

ULTRASOUND ASSESSMENT OF VENOUS THROMBOEMBOLISM

There are several circumstances in which an intensivist may wish to search for Deep Vein Thrombosis (DVT). These include physical examination findings that suggest DVT or an acute deterioration of respiratory or circulatory status where DVT is sought as a surrogate marker for PE. Deep vein thrombosis may be observed as an incidental finding while examining veins for cannulation. When the intensivists decide to obtain a study for DVT, they have two choices, either they may call for a study being performed by a vascular technician/radiologist or they may choose to perform the study themselves at point-of-care. Waiting for a radiology performed study introduces a dangerous delay in the process of diagnosis and management of DVT. Intensivists and other nonradiologists may perform DVT study with the same level of accuracy as radiology department based services.[95,96] The study technique is easy to learn and has immediate bedside application. The intensivist who is skilled at DVT study can obtain immediate diagnosis very rapidly at bedside.

Equipment

Modern portable bedside ultrasound machines, equipped with a high frequency linear vascular transducer, are suitable to detect DVT. Doppler capability, while desirable, is not a requirement in order to perform an accurate study; DVT can be diagnosed using 2-D compression ultrasonography alone.[97,98]

Examination Protocol

For lower extremity examination, if possible, the patient should be placed in reverse Trendelenberg position with the leg externally rotated and the knee slightly flexed. The examination should be bilateral and comparative. The examination starts at the level of the inguinal ligament (femoral crease) where the external iliac vein becomes the common femoral vein. Careful consideration should be given to the area where the great saphenous vein drains into the common femoral vein. The common femoral vein is scanned at multiple points up to its bifurcation into the superficial femoral vein and the deep femoral veins. The superficial vein is examined at multiple points until it enters the adductor canal. The popliteal vein is assessed where it runs behind the knee joint, in the popliteal fossa. In the upper extremity and neck vein examination, the veins are imaged at regular intervals in transverse plane along their course to avoid missing a clot.[99,100] While compressions on transverse scan are used for internal jugular, axillary and brachial veins, the subclavian vein cannot be compressed effectively so that Doppler study may be necessary. After obtaining a satisfactory picture on a transverse scan, the transducer can be rotated 90° to get a longitudinal image of the vessel, suitable for rapid survey of veins and assessment of extent and nature of a thrombus when seen.

At each site of examination, the vein is identified by its location, by the company of an artery and on occasions by visualizing valve movement within the vein. Before compression, the vein is examined for visible clot, seen as distinct echogenic material that can be mobile and/or adherent to the vessel wall. Visible clot is diagnostic of

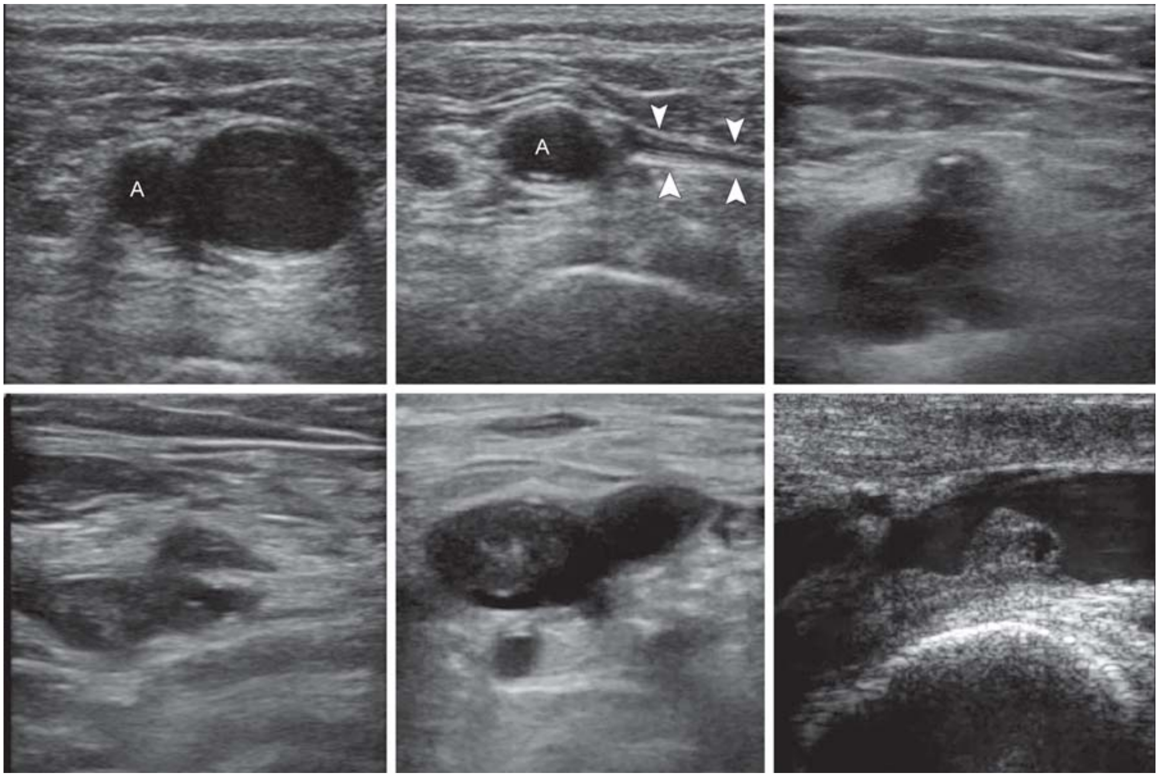


Fig. 144.26: Ultrasonography in the diagnosis of DVT

Upper left panel: A normal common femoral vein before compression (A= Arterial lumen). Upper right panel: A normal common femoral vein after compression. Note the complete obliteration of venous lumen on application of compression (arrowheads).
Upper middle panel: Common femoral vein DVT before compression.
Middle panel, right: Common femoral vein DVT after compression. Note that the lumen cannot be obliterated. The thrombus is also visible as echogenic material within the venous lumen after compression.
Lower panel, left: Common femoral vein thrombosis. The thrombus is visible within the venous lumen. Compression should not be applied if the thrombus is already visible. Lower middle panel: A longitudinal view of the common femoral vein shows the clot

DVT; (Fig. 144.26, lower panel); no compression maneuver is required in this circumstance. If no clot is visualized, the examiner applies sufficient pressure to deform the vein. A normal vein is compressible with mild pressure (0.5–1.0 kg/cm^2). Complete compressibility is defined as apposition of walls with effacement of lumen (Fig. 144.26, upper panel) Complete compressibility excludes DVT at the site of examination. Incomplete compressibility of vein indicates presence of DVT and is the only validated diagnostic criterion for DVT. Abnormal compression ultrasonography (Fig. 144.26, middle panel) has high sensitivity and specificity for diagnosis of femoropopliteal DVT.[101,102]

Clinical Issues

Deep vein thrombosis as a surrogate marker for PE: Compression ultrasonography shows a DVT in 30–50% of patients with PE. Finding a proximal DVT in patients suspected of PE is sufficient to start anticoagulion treatment without further testing.[103,104]

Importance/frequency of upper extremity DVT: About 10% of all cases of upper extremity DVT have been reported to result in pulmonary embolism.[105] Certain groups of patients are more prone to develop upper extremity DVT such as cancer patients with central venous port systems,[106] patients with peripherally inserted central venous catheters[107] and patients with central venous catheters (both internal jugular, axillary/subclavian).[108,109] Few studies have examined ultrasonography for the diagnosis of upper extremity DVT. These studies are of inferior methodology. In the absence of a good alternative test in ICU patients, compression ultrasonography remains a practical choice for diagnosis of upper extremity DVT.[110]

Importance of studying calf veins: Ultrasound study of calf veins for DVT requires operator experience, significant additional time and difficulties in positioning the patient. The accuracy of ultrasonography in the diagnosis of calf DVT has been reported to be lower than in the diagnosis of proximal DVT.[111] Our opinion is that it is not realistic for intensivists to develop this skill level. One strategy is for the intensivist to repeat the DVT study of the popliteal and femoral veins serially at 24–48 hours in those patients who are very high risk for DVT.

DVT proximal to femoral veins: In non-trauma patients, isolated iliac vein or IVC thrombosis is very uncommon, but is always a concern especially in cases of previous femoral vein cannulation.[112] These veins may not readily be imaged with ultrasonography except in patients with slender body habitus. In trauma patients, as well as in patients with pelvic disorders and obstetric patients, isolated pelvic vein thrombosis may need to be explored with use of Doppler or other imaging modalities.

Limitations

1. The examiner must have adequate training and familiarity with the venous anatomy.
2. Patients who are obese, edematous, or who have wounds or dressings may have inadequate image quality.
3. The identification of a thrombus does not indicate its age. There are criteria that can be used to identify recent or old (presumably) inactive thrombi. However, these are not completely reliable.
4. The subclavian vein may not be compressible particularly in obese or muscular individuals. Unless an echogenic clot is visualized within the subclavian vein, lack of compressibility does not necessarily indicate the presence of an isoechoic clot within the subclavian vein.

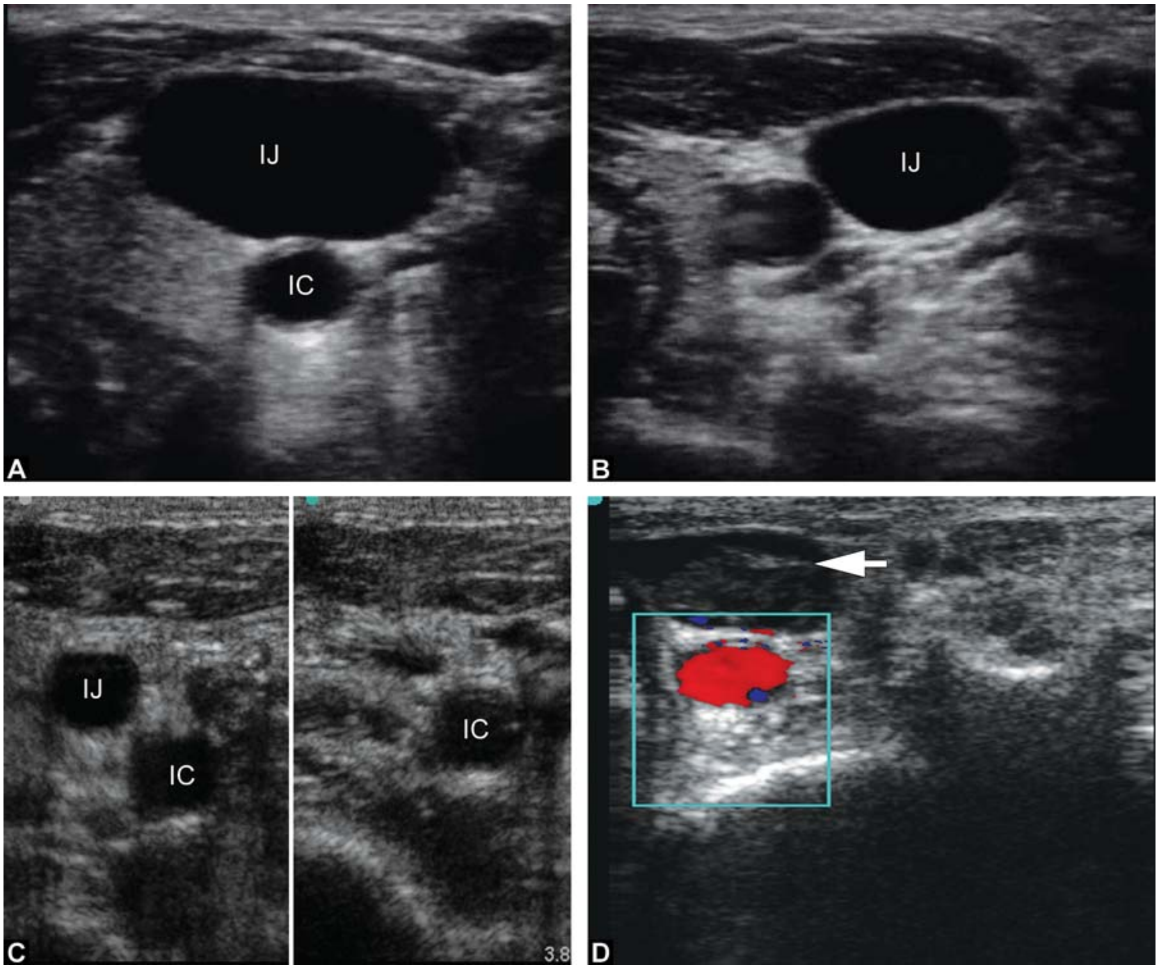
ULTRASOUND GUIDANCE FOR PROCEDURES

Ultrasound Guided Vascular Access

Ultrasonography may be used to guide vascular access in the ICU. Several studies and two meta-analyses have shown the benefits of ultrasound guidance in central venous catheter placement.[113-116] Ultrasound guidance for central venous access is recommended by national quality organizations in the United States and the United Kingdom.[117,118] It improves success and reduces complication rate for central venous access and can be used for arterial and peripheral vascular access. In this section, we will discuss the general principles for performing vascular access under ultrasound guidance. This discussion assumes that the reader has full knowledge of the mechanical aspects of vascular access such as site preparation and physical manipulation of needle, dilator and cannula. For detailed site specific discussion, the reader is referred to comprehensive review articles.[119-121]

Advantages of Using Ultrasound to Guide Vascular Access

- *Localization of vessels:* Following identification of the anatomical landmarks, prepuncture ultrasound examination of the proposed site helps in the identification of the target vessel and its relationship with surrounding structures (e.g. carotid artery, thyroid gland and trachea in case of internal jugular vein cannulation). The ultrasound images are used to identify anatomical variations and to fine tune the selection of the puncture site (Fig. 144.27A and B).
- *Assessment of suitability for vascular cannulation:* Examination of the target vessel allows for determination that the vessel is suitable for line placement. Ultrasonography permits visualization of features that prohibit vascular access which cannot be identified by simple visual examination. There may be marked difference in vessel caliber (Fig. 144.27C)[122,123] and variability of vessel position relative to the adjacent artery in approximately 5% of the general population.[124,125] A partial or complete thrombosis of the vessel, a vascular stenosis or a perivascular hematoma, can only be identified with ultrasonography (Fig. 144.27C). Hypovolemia may reduce the size of target vessel and marked respiratory efforts may cause variability of vascular size (Fig. 144.27D), making it impossible to cannulate the internal jugular and subclavian veins. These cannot be identified without ultrasonography. Use of ultrasound, therefore, reduces the chances of failure associated with blind technique.
- *Reduction of procedure time:* Ultrasound guidance of central venous access reduces the number of attempts required and improves first-pass success rate, improving the safety and comfort of the patient.
- *Use in arterial puncture and peripheral venous access:* Ultrasonography is useful in guiding all forms of arterial access and is particularly useful in patients who are hypovolemic or hypotensive, or who develop vasospasm secondary to multiple cannulation



Figs 144.27A to D: Ultrasonography helps in selection of a suitable vessel for cannulation: A. Internal jugular vein (IJ) is located directly in front of the internal carotid artery (IC). Attempted cannulation at this site will carry high risk of inadvertent puncture of the carotid artery. B. As the internal jugular vein is imaged at different points along its course in the neck, at this location the vein lies outside the carotid artery. Attempted venous puncture will not have much risk of accidental carotid artery puncture. C. Small left IJ with near complete obliteration of the lumen during spontaneous breathing. Cannulation of this vessel will be very difficult. D. IJ thrombus (arrow). Note that the thrombosed IJ does not show any color flow signal while the carotid artery does

attempts.[126,127] The diameter of the radial artery is only approximately 3 mm,[128] so that blind line insertion at this site may be challenging. Ultrasound guidance improves success rate of peripheral venous access.[129,130]

- *Evaluation of potential complication:* Ultrasonography may be used to immediately identify procedural complications of vascular access such as hematoma or pneumothorax. Ultrasonography may be used to confirm guidewire placement prior to dilatation. This is useful to avoid inadvertent arterial injury during central venous access. The correct placement of the guide wire and catheter can be checked immediately at bedside (Fig. 144.28, right upper panel and lower panel).

Equipment Requirement

- Vascular access is generally performed by using a high frequency (7–10 MHz) linear transducer. The higher frequency provides excellent resolution with the trade off that penetration is limited. Fortunately, barring massive obesity, vessels commonly accessed for cannulation, are superficial.
- In performing real-time ultrasound guidance of vascular access, the use of a purpose designed sterile probe cover is mandatory. An attempt to jerry-rig a sterile transducer cover using a glove, is inappropriate and violates basic principles of central line sterile precautions.

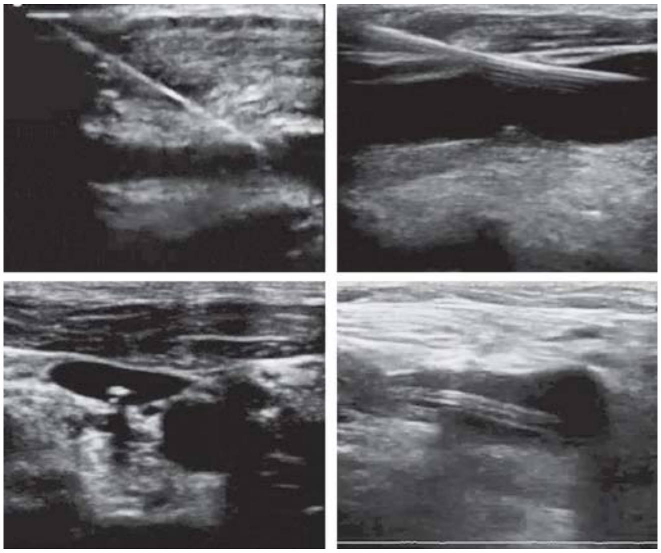


Fig. 144.28: Vascular cannulation under ultrasound guidance

Left upper panel: Subclavian vein is punctured under ultrasound guidance. The vein is visualized in the long axis and the needle trajectory is under direct visual control.

Right upper panel: Correct placement of guide wire is confirmed before dilatation.

Left lower panel: Correct placement of catheter can easily be confirmed using ultrasound. A cross sectional view of IJ shows the catheter inside the vascular lumen.

Right lower panel: The catheter can also be visualized inside the vein in longitudinal view.

General Principles of Ultrasound Guidance of Vascular Access

- In addition to full mastery of machine control and transducer manipulation, the operator must place the machine in such a way that the screen is easily visible without much movement on the part of the operator. This might require rearrangement of equipment and bed position in a crowded work environment. The operator should avoid a situation where the screen is not easily visible.
- The operator must have knowledge of local anatomy. With the understanding of the anatomy, a key objective of using ultrasonography is to unequivocally identify the target and to differentiate veins from arteries. A vein is identified initially by its typical location and relationship with the surrounding structures. Once identified, the operator must confirm that the vascular structure is in fact a vein. The vein is easily compressible whereas the adjacent artery is not. The vein has respirophasic change of caliber and may have mobile venous valves that are visible with ultrasonography. Performance of Valsalva maneuver increases caliber of the vein but has no effect on caliber of the artery. The artery is pulsatile. In general Doppler analysis is not required to differentiate veins from arteries with the exception of subclavian position. In the subclavian position, particularly in muscular or obese individuals, compression of subclavian vein may be difficult; venous valve and respirophasic change may also be difficult to recognize. Doppler may be used to identify subclavian vein.
- Before performing subclavian or internal jugular venous access, the contralateral vein should be examined in order to identify the best site in terms of vessel position, size and condition. In addition, the operator should document the presence of sliding lung bilaterally before starting the procedure in order to rule out pneumothorax.
- Following insertion of the guide wire and before dilatation of the vessel, the operator should always document that the guide wire is in the vein (Fig. 144.28, right upper panel). Inadvertent placement of a guide wire into the adjacent artery is of no clinical consequence as the vessel defect is small. The wire may be removed with local vascular compression to follow. However, inadvertent dilatation of the artery due to unrecognized wire insertion leaves a much larger defect and constitutes a major complication.
- Following the procedure, the operator should document sliding lung. Its presence rules out procedural pneumothorax. Loss of lung sliding following internal jugular or subclavian venous access, where it was known to be present before the procedure, is a strong evidence of procedure related pneumothorax.

Technique for Vascular Cannulation

There are two general approaches to ultrasound guidance for vascular access, the short axis and the long axis approach.

Using the short axis approach, the transducer is oriented such that the image shows a cross-sectional view of the vessel. The needle is inserted at a point away from the transducer and angled towards the center of the image. Some operators track the needle tip as it moves forward by moving the transducer along with the needle in synchrony, thereby guiding the needle tip real-time in the vessel. The alternative is to hold the transducer in a stable position and estimate the angle and depth in which the needle should be inserted in order that the needle tip intersect the scanning plane in the lumen (center) of the target vessel. Neither method is known to be superior to the other and should be used according to operator preference.

Using the long axis approach, the transducer is oriented such that the image shows a longitudinal image of the vessel. The needle is introduced at the side of the transducer and advanced so that the entire needle is visualized throughout the insertion process (Fig. 144.28, left upper panel).

At internal jugular and femoral insertion sites, both short axis and long axis approaches are effective. In the authors' experience, scanning the vessel in transverse axis is the preferred method for accessing femoral and IJ vein. Most operators prefer to use this approach. Final choice should be predicated to operator experience.

Specific Issues Related to Access Site

Internal jugular vein (IJV): In the authors' experience, most operators image the jugular vein in its transverse axis, although some prefer a longitudinal approach.[131] In using ultrasound for guidance of IJV access, it becomes clear that the landmark based blind posterior approach places the carotid artery deep to the IJ vein. This risks inadvertent puncture of the carotid artery as the needle can easily pass through the IJV. The anterior approach is favored when using ultrasound guidance as a point of puncture can be chosen, so that the vein is positioned lateral to the artery. This underlines one major advantage of using ultrasound for vascular access; the angle of needle insertion is determined by the image rather than relying on blind landmark method.

Subclavian vein: Traditional landmark based technique requires the operator to use the clavicle as the definitive landmark for the procedure. When using the ultrasound for subclavian vein access, the operator should choose a much more lateral position for insertion than is used for blind technique.[132] Using ultrasound, the vein may be punctured near the point where the axillary vein becomes the subclavian vein (before it crosses the outer border of first rib). The vein in this location is more caudal and superficial. Several advantages of this ultrasound guided (more lateral) axillary vein puncture over traditional blind subclavian puncture have been suggested which are as follows:

a. There is a reduction of accidental arterial punctures.
b. There is less discomfort, as there is no contact of the needle with the periosteum of the clavicle.
c. The catheter enters the vein well before the vein passes the narrow space between first rib and clavicle, so there is a less risk of pinching and transection of the catheter.[133]
d. With ultrasound guidance, the vein can be entered close to the clavicle; here we have the attachment of the vein to the clavicle preventing the anterior wall from collapsing during puncture.[120]
e. After the guide wire is placed, the distal internal jugular vein can be examined; if the wire is seen into IJ vein, it can be repositioned under ultrasound guidance.[134]

Subclavian venous access under ultrasound guidance is best performed with the vessel imaged in longitudinal axis (Fig. 144.28, left upper panel). In this way, the needle can be visualized in its entirety throughout the insertion. This level of needle control is important as the pleural surface is close to posterior vessel wall.

Femoral vein: The femoral vein is usually accessed using transverse imaging axis. If the image plane is below the inguinal ligament, the vein will be positioned deep to the artery. This is inappropriate position for access, as there is high risk for arterial injury. The transducer position should be adjusted such that the common femoral vein is imaged medial to the artery. Slight external rotation of the leg helps to bring the vessels side by side.

Arterial catheterization: Ultrasound guided radial artery cannulation has been shown to have a higher success rate than blind technique.[127] Radial artery cannulation may be difficult at the standard wrist site due to vasospasm, hematoma formation, or intimal dissection after repeated attempts. In these cases, successful cannulation of the radial artery at a more proximal (mid forearm) location, deep to the brachioradialis muscle, has been reported using real-time ultrasonography.[135] Femoral artery cannulation is similar to central venous line placement at this site in terms of ultrasound technique.[136] Ultrasound may identify significant atheromata at the femoral artery precluding that site.

Peripheral venous cannulation: For those patients who have difficult peripheral venous access, ultrasound improves the success rate, reduces the number of unsuccessful attempts, requires less time and improves patient satisfaction.[129,130]

ULTRASOUND GUIDANCE OF THORACENTESIS

Ultrasonography may be used to guide thoracentesis with improved success and reduced pneumothorax rate.[137] Ultrasound guidance for thoracentesis is important in the ICU as standard supine chest radiographs have severe limitations in identification of a safe site for needle insertion. In the patient on mechanical ventilatory support, a pneumothorax resulting from a thoracentesis effort may have catastrophic complications. Several studies have addressed the safety of US for guidance of thoracentesis in mechanically ventilated patients and have shown that the procedure may be performed with a low complication rate.[32,138]

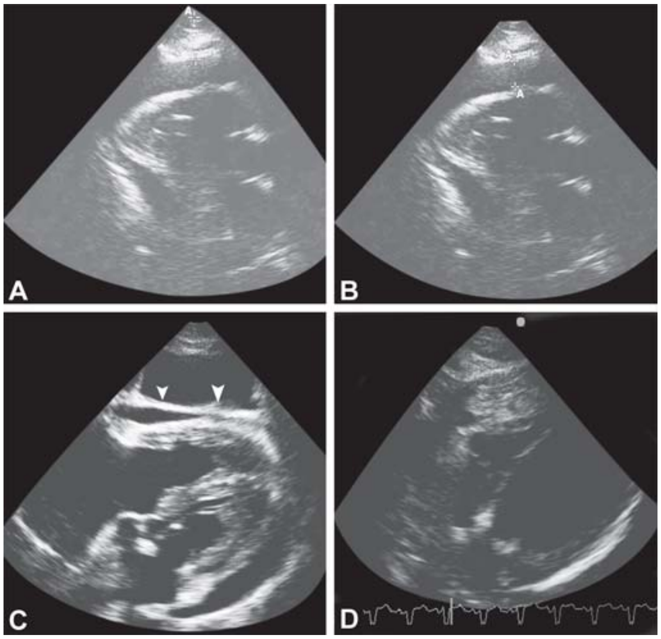
The purpose of ultrasonography for procedural guidance of thoracentesis is to identify a safe site, angle and depth for needle penetration that avoids injury to lung, subdiaphragmatic organs and the heart. The critically ill patient is often supine, so by gravitational effect the pleural fluid takes a dependent posterior position in the thorax (unless loculated). The scanning plane should be in the longitudinal axis in the posterior to mid-axillary line. The transducer is angled and/or moved to find an anechoic space that is subtended by typical anatomical boundaries and that has typical dynamic findings, consistent with a pleural effusion. Before any consideration of needle insertion, the examiner must make unequivocal identification of the diaphragm. The neophyte ultrasonograpgher may misidentify the hepatorenal or splenorenal space, which is curvilinear as the diaphragm. This is a serious error, as this could lead to laceration of these organs. There should be at least 10 mm space between the inside of chest wall and the visceral pleural surface.[32,138] Once a suitable site is identified and marked, the depth of the penetration is measured from a frozen ultrasound image. Thoracentesis should be performed promptly after ultrasound marking without any patient movement to avoid shifting of fluid from the intended aspiration site. The syringe and the needle assembly should be introduced in the same angle in which the transducer was held while determining the best access site. This is best accomplished when the operator performs the procedure immediately following the examination. Following the procedure, the operator should check for pneumothorax by examining for lung sliding.[139] Ultrasound guidance of needle insertion may be used for simple thoracentesis or for insertion of pleural drainage system of any size.

An important pitfall is that firm pressure by the probe on the skin, particularly in an edematous patient, may indent the skin at the site of examination. This leads to the underestimation of the depth at which fluid will be reached when aspiration is attempted. The operator should be able to recognize this problem and needs to insert the needle more than the measured distance.

ULTRASOUND GUIDANCE OF PERICARDIOCENTESIS

Echocardiography guided pericardiocentesis is the current standard of care for drainage of pericardial effusion. The traditional subxiphoid approach to pericardiocentesis, with or without fluoroscopic guidance should be replaced in favor of ultrasound guided pericardiocentesis.[140] In a report of 1127 consecutive echocardiography guided pericardiocenteses, success was achieved in 97% cases, including 89% cases, where fluid could be obtained with a single needle pass. Major complications (chamber laceration or injury to an intercostal vessel necessitating surgery, pneumothoraces requiring chest tube placement, ventricular tachycardia and bacteremia) were reported in 1.2% cases with death of one patient.[141] Similar success rate has been reported in another large series.[142]

To perform pericardiocentesis under ultrasound guidance, the examiner scans using multiple windows in order to determine a safe site, angle and depth of needle penetration (Figs 144.29A and B). The ideal entry site is the point where the largest collection of fluid can be reached by the shortest distance from the skin following a straight trajectory and avoiding any vital structure.[140] Under ultrasound guidance, the left anterior chest wall is the entry site of the needle in the majority of the cases. The subxiphoid approach is often not indicated as the effusion is not of sufficient size or the liver blocks safe needle insertion. The patient's body position may be shifted in order to redistribute the pericardial fluid for better access. At least 10 mm of fluid depth is required to perform safe pericardiocentesis. The heart may exhibit marked movement both in swinging form as well as between systole and diastole, so that the safe depth of needle penetration needs to be measured within the context of cardiac movement. Once the clinician marks the site for access, the patient should not move until the procedure is performed, out of concern that patient movement will cause redistribution of fluid within the pericardium. The site is prepared with sterile technique and all equipment is prepared. A sterile transducer cover should be included in the set up. After the preparation and before needle insertion, the intensivist performs a confirmatory scan to document the best site, angle and depth for needle insertion. Real-time guidance of needle insertion is not required for pericardiocentesis (similar to thoracentesis), provided the operator performs the scan immediately before the needle insertion. The needle and syringe assembly is held in the angle in which the transducer was held. Skin



Figs 144.29A to D: Pericardiocentesis under ultrasound guidance. A & B: Large pericardial effusion. In PSL view, anterior effusion of 1.91 cm thickness was seen at a depth of 3.16 cm from the skin. Pericardiocentesis was performed from left parasternal access. C: The drainage catheter in the pericardial space (arrowhead) shown in the subcostal view. D: Injection of agitated saline through the catheter helped to confirm the position of the catheter by opacification of the percardial space

compression artifact may be problematic. This occurs when the transducer is applied firmly to the skin of the patient so that the measured depth underestimates the depth required to access fluid. The operator must take care to avoid asymmetric force application to the skin mark, as this may cause an inaccurate site of insertion. Placing a depth guard on the needle and introducing the needle in a straight line without any lateral movement ensure further safety of needle advancement. Once the needle has penetrated the pericardial fluid space, a wire and/or catheter may be introduced with prompt removal of the needle. The final catheter type is up to the discretion of the operator. The catheter position may be confirmed either by directly identifying the catheter within the pericardial space (Fig. 144.29C) or by injecting agitated saline through the catheter and visualizing the same in the pericardial space (Fig. 144.29D).

ULTRASOUND GUIDANCE OF PARACENTESIS

Diagnostic and therapeutic paracentesis are common procedures performed in intensive care units. Often, paracentesis is performed by a blind technique with reliance on physical examination to identify a suitable site. The safety and success of paracentesis can be improved by use of ultrasonography.[143] Ultrasound guidance of paracentesis is preferable under certain circumstances such as advanced pregnancy, significant bowel distension and extensive/multiple previous abdominal surgeries. The blind paracentesis is relatively contraindicated if any of these conditions are present.[144] In patients who have peritoneal adhesions from previous surgeries or peritonitis, the fluid may not be located at typical abdominal sites where blind paracentesis is attempted. The chance of success with blind paracentesis depends on the amount of fluid present. In patients who have a small amount of fluid, ultrasonography helps to confirm the presence of fluid and locate the best site for performing the procedure. In some patients thought to have ascites by clinical examination, ultrasonography may negate the presence of the same or may show too little fluid for safe paracentesis. Ultrasonography reduces unsuccessful blind attempts.[145]

Ultrasound guided paracentesis uses the same skill set required to perform thoracentesis and pericardiocentesis. The operator scans the lower lateral abdomen and suprapubic area in order to indentify the best site, angle and depth for needle entry. The epigastric artery runs in the lateral rectus sheath and is generally sufficiently medial in position that it is not at risk for inadvertent needle injury. For maximal safety, the operator may examine the proposed insertion site for aberrant vascular structures. Ascites has its mimics; a distended bladder or fluid filled intestinal structures may be mistaken for ascites. They have anatomic patterns that allow the operator to differentiate from intra-abdominal fluid. Ascites changes in shape when the transducer is pushed into the abdominal wall. Like thoracentesis and pericardiocentesis, paracentesis need not be performed with real-time guidance provided the operator performs the procedure immediately following site identification without any interval patient movement. For ultrasound guidance of paracentesis, a suitable site is one where a collection of fluid is seen and a straight path of approach to the fluid from the skin surface avoids bowel loops and other organs.

ULTRASOUND FOR AIRWAY MANAGEMENT

Ultrasonography can be helpful in airway management of critically ill patients.[146] It has been studied for preintubation measurement of anterior neck soft tissue thickness, particularly in obese patients, showing positive correlation with difficulty in laryngoscopy.[147]

Ultrasonography can be used to confirm endotracheal intubation in two ways. By obtaining a midline longitudinal section of the trachea at the level of the cricoid cartilage, the endotracheal tube can be visualized as an echogenic line below the anterior tracheal wall. Whereas the endotracheal position of the tube can be confirmed, it is not possible to determine where the tip of the endotracheal tube is located. As an alternative, the presence of bilateral lung sliding and diaphragmatic movement with ventilation confirm endotracheal tube position. Ultrasonography may also be used to identify inadvertent main stem bronchial intubation. In this case, if the endotracheal tube has been advanced to right main stem bronchus with the inflated cuff blocking air entry to left, the patient will exhibit lung sliding with ventilation on right side but will lack the same on the left side as no air entry occurs. The patient will have lung pulse on the left.[14] Very soon after the main stem intubation, the left lung will develop resorptive atelectasis, particularly if the patient is on high FiO_2; the left lung will develop consolidation pattern on ultrasonography. Drawing back of the ETT may be guided by lung ultrasonography.

Ultrasonography has been studied to predict extubation outcome. The degree of diaphragmatic movement during spontaneous breathing trial, measured as displacement of liver/spleen, has been reported to have more accuracy in predicting successful extubation than traditional weaning parameters.[148]

Ultrasonography has been used to guide percutaneous dilatational tracheostomy.[149-151] Ultrasound study of the thyroid and cricoid cartilages, tracheal rings, paratracheal soft tissues, thyroid gland and vascular structures allows the intensivist to select the optimal puncture site of the trachea. The identification of a large aberrant midline vein or an innominate artery that is unusually high in position allows the intensivist to avoid catastrophic complication of major vessel injury. With the help of ultrasonography, patients who have unfavorable anatomy for percutaneous dilatational tracheostomy can be identified and referred for surgical tracheostomy.[152]

During emergency endotracheal intubation, unrecognized gastric fluid collection may result in life-threatening aspiration event. Ultrasonography can be used to rapidly identify a significant gastric fluid collection during set up of emergency ETT (Fig. 144.25I). This allows the team to empty the stomach with the insertion of a gastric tube, thereby avoiding the risk of dangerous aspiration event. If the patient is too unstable for gastric tube insertion, the team may take specific measures to prevent aspiration of gastric contents with the fore knowledge of the risk.

ULTRASOUND FOR CONFIRMATION OF GASTRIC TUBE PLACEMENT

Ultrasonography can be used to confirm the proper location of a gastric tube. By scanning the left upper quadrant, the gastric tube may be seen as a discreet structure. Injection of air or fluid yields a characteristic pattern of air bubbles within the stomach. Bedside ultrasonography has been used to guide placement of nasoenteric feeding tubes[153,154] and to replace dislodged gastrostomy tubes.[155] The tip of the tube is visualized with ultrasonography; visualization can be improved by injecting air through the tube as air acts as a contrast for ultrasound imaging.[154]

LUMBAR PUNCTURE

Use of ultrasonography to facilitate spinal puncture has been reported in obstetric anesthesia literature. Using an initial paramedian longitudinal scan plane approach, the level of vertebral interspaces such as L5-S1, L4-L5 are identified and marked. A transverse scan of each individual space is then performed. The processes flanking each vertebral interspace are identified as small hyperechoic signals. When the plane of transverse scanning passes exactly through an interspace, a hyperechoic band-like shadow of the ligamentum flavum and the dorsal dura is visualized. The best site, angle and depth of puncture can be accurately judged. Use of ultrasound decreases procedure time and improves patient comfort.[156]

OTHER PROCEDURES

Ultrasonography allows for accurate placement of needle, wire or a drainage device into a wide variety of clinically important targets. For example, abscesses, lymph nodes, lung masses, mediastinal masses and fluid collections of all types may be accessed under ultrasound control. The principles of ultrasound guidance remain the same regardless of the procedure. The operator identifies the target and adjacent anatomic structures that must be avoided during the needle insertion. The best site, angle and depth are determined. In many cases, real-time control is not necessary. For small targets, the operator must be proficient with real-time guidance. In the authors' experience, this is best done with the needle being scanned in its entirety along its long axis throughout insertion. Entry of needle into the target allows for simple aspiration or biopsy or may be followed by the drainage device of operator's choice.

CONCLUSION

Ultrasonography has major utility in critical care medicine. High quality portable machines are widely available and permit point of care scanning by the frontline intensivist. Ultrasound imaging of the lung, pleura, vascular structures, heart and abdominal organs allow rapid diagnosis and guides management at the bedside of the critically ill patient. Ultrasonography increases the safety and success rate of many common ICU procedures. We hope that this chapter serves to inform and motivate the intensivists to develop competence in the field of CCUS as defined in the ACCP-SRLF statement on competence in the field.
